Table 5 Typical lithium ion conductors

Mobile ion	Composition	Conductivity (25°C) ($S\text{ cm}^{-1}$)	Note
Li^+	Li_3N	3×10^{-3}	
	$\text{La}_{0.25}\text{Li}_{0.18}\text{TiO}_3$	1×10^{-3}	LLT
	$\text{Li}_{2+2x}\text{Zn}_{1-x}(\text{GeO}_4)_4$	2×10^{-6}	LISICON
	$\text{Li}_{10}\text{GeP}_2\text{S}_{12}$	1.2×10^{-3}	Thio-LISICON
	$\text{Li}_2(\text{BH}_4)(\text{NH}_2)$	2×10^{-4}	Hydride
	$\text{Li}_2\text{O} \cdot 11\text{Al}_2\text{O}_3$	10^{-3}	Li- β -Alumina
	$\text{Li}_{1.55}\text{Ti}_{1.75}\text{Al}_{0.25}\text{Si}_{0.3}\text{P}_{2.7}\text{O}_{12}$	1.2×10^{-3}	OHARA glass
	$\text{Li}_7\text{La}_3\text{Zr}_2\text{O}_{12}$	10^{-4}	LLZ
	$\text{Li}_3\text{PO}_3.9\text{N}_{0.17}$	2×10^{-6}	LIPON
	$\text{Li}_{3-2x}(\text{In}_{1-x}\text{M}_x)_2(\text{PO}_4)_3$	10^{-5}	
	$37\text{Li}_2\text{S} \cdot 18\text{P}_2\text{S}_5 \cdot 45\text{LiI}$	10^{-3}	Glass
	$50\text{LiI} \cdot 50\text{Al}_2\text{O}_3$	3×10^{-4}	Mesoporous composite
	$\text{PEO} \cdot \text{LiClO}_4$	10^{-5}	Polymer

the polymer electrolytes is around 10^{-4} S cm^{-1} at room temperature although the transference number of the lithium is less than 0.5 and the counter anion is much higher.

Proton (or Hydride Ion) Conductors

A good proton-conducting solid would be a promising material for future hydrogen energy systems. They will be of use as a solid electrolyte for fuel cells, hydrogen production, hydrogen separation, hydrogen sensors, and membrane reactors. Various kinds of proton conducting solids have been synthesized. They are roughly classified into six categories as represented in Table 6 with typical compounds belonging to each category. Hydrated heteropoly acids such as $\text{H}_3\text{Mo}_{12}\text{PO}_{40} \cdot 29\text{H}_2\text{O}$ and $\text{H}_3\text{W}_{12}\text{PO}_{40} \cdot 29\text{H}_2\text{O}$ show very high protonic conductivity at room temperature. However, they are unstable at elevated temperatures even below 100°C to loose the water molecules to decrease in their conductivity. The conductivity of CsHSO_4 , which is an anhydrous compound, increases at 144°C due to transformation of its crystal structure. Some related materials as $\text{M}_3\text{H}(\text{XO}_4)_2$ ($\text{M}=\text{Rb}, \text{Cs}, \text{NH}_4$; $\text{X}=\text{S}, \text{Se}$) or phosphates have been known to show high proton conductivity up to 10^{-2} S cm^{-1} at around 200°C "superprotonic" state. A typical structure of the superprotonic state is shown in Fig. 9 for CsH_2PO_4 , where the PO_4 is rotating very fast to promote the proton jump between the two oxygens.

The charge carriers in H_3O^+ β'' -alumina and NH_3^+ β'' -alumina are considered to be partly protons and partly hydronium or NH_4^+ must be replaced for Na^+ by ion exchange of conventional $\text{Na-}\beta''$ alumina. It is known that the mobility of protons in H_xWO_3 and H_xMoO_3 is very high. But the conductivity itself cannot be measured since electronic conduction in these oxides is much higher than that of protons.

Organic polymers based on polyethyleneoxide or polyvinylalcohol with inorganic acid shows proton conduction, the conductivities of which are the order of $1 \times 10^{-4}\text{ S cm}^{-1}$ at room temperature.

Table 6 Typical solid proton conductors

Category and material	Conductivity ($S\text{ cm}^{-1}$)	Note
<i>Hydrate compounds</i>		
$\text{H}_3\text{Mo}_{12}\text{PO}_{40} \cdot 29\text{H}_2\text{O}$	2×10^{-1} (25°C)	Room temperature type. Unstable at dry atmosphere
$\text{H}_3\text{W}_{12}\text{PO}_{40} \cdot 29\text{H}_2\text{O}$	2×10^{-1} (25°C)	
$\text{HUO}_2\text{PO}_4 \cdot 4\text{H}_2\text{O}$	4×10^{-3} (20°C)	
$\text{HClO}_4 \cdot \text{H}_2\text{O}$	3×10^{-4} (27°C)

<i>Organic polymers-inorganic acids</i>		
$\text{PEO-H}_2\text{SO}_4$	2×10^{-4} (25°C)	Polyethylene oxide
$\text{PVA-H}_3\text{PO}_4$	$1 \times 10^{-5} \sim 1 \times 10^{-3}$ (25°C)	

Development of proton conducting ceramics which are stable over a wide range of temperature has been desired because they are very useful materials for electrochemical energy conversion and sensors (see Section on Application Examples). Some doped perovskite-type oxide solid solutions based on SrCeO_3 and BaCeO_3 are known to exhibit appreciable protonic conduction under a hydrogen-containing atmosphere at elevated temperatures. $\text{SrCe}_{0.95}\text{Yb}_{0.05}\text{O}_{3-\delta}$ and $\text{BaCe}_{0.9}\text{Y}_{0.1}\text{O}_{3-\delta}$ belong to this class of proton conductors. These ceramics exhibit only p type electronic conduction in the atmosphere free from water vapor or hydrogen. However, when water vapor or hydrogen is introduced into the atmosphere at high temperature, electronic conductivity decreases and protonic conduction occurs rapidly. When the SrCeO_3 based ceramics are exposed to hydrogen gas at high temperature, they become almost pure protonic conductors, the conductivity of which is about $1 \times 10^{-2} S\text{ cm}^{-1}$ at 900°C (somewhat lower than that of YSZ shown in Fig. 1). Since zirconate-based ceramic $\text{CaZr}_{0.9}\text{In}_{0.1}\text{O}_{3-\delta}$ exhibits proton conduction and their mechanical strength as well as chemical stability is better than those of cerates, they are used as a solid electrolyte for hydrogen sensors (see Section on Application Examples) although its conductivity is rather low.

It is necessary to add some recent reports on hydride ion conductors. The existence and possible transport of hydride ion (H^-) in some oxides are reported in $12\text{CaO}-7\text{Al}_2\text{O}_3$ (Hayashi *et al.*, 2002), $\text{BaTiO}_{2.4}\text{H}_{0.6}$ (Yoji Kobayashi *et al.*, 2012), La_2LiHO_3 etc. (Kobayashi *et al.*, 2016; $\sigma = 10^{-6} S\text{ cm}^{-1}$ at 500K), in which the observed ionic conductivity is reported not due to the proton (H^+) conduction but by hydride ion (H^-). The size of the H^- ion is about 1.2 Å, which is suitable for ionic conduction. Although some critical discussions are still going (Norby *et al.*, 2004), these materials might open a new frontier of ionics field (Table 7).

Other Cation Conductors

Some other cations are conducting in solids, although their conductivity is rather low; for example, potassium ions K^+ can move in the tunnel-structured oxide $\text{K}_2\text{O}_{5.2}\text{Fe}_2\text{O}_{30.8}\text{ZnO}$. Divalent cation conductors $\text{M}^{(\text{II})}\text{Zr}_4(\text{PO}_4)_6$ are known, where $\text{M}^{(\text{II})}$ is Mg^{2+} , Zn^{2+} , Mn^{2+} etc.; for example, $\text{MgZr}_4(\text{PO}_4)_6$ has the Mg^{2+} ion conductivity of $3.4 \times 10^{-3} S\text{ cm}^{-1}$ at 800°C (Nomura *et al.*, 1992). As was shown in the previous sections, β - and β'' -alumina are capable to allow many kinds of cations to migrate in its conduction planes; for example, Ba^{2+} , Cd^{2+} , Sr^{2+} , Eu^{2+} , most of which are prepared by exchanging Na^+ ions with those ions. Trivalent cations of Sc^{3+} and Al^{3+} were reported mobile in $\text{Sc}(\text{WO}_4)_3$ and $\text{Al}(\text{WO}_4)_3$ respectively, although their conductivities are rather low $10^{-5} S\text{ cm}^{-1}$ at 600°C (see Table 1).

Fig. 9 Structure model of CsH_2PO_4 (from Haile *et al.*, 2007).

Fluoride and Chloride Ion Conductors

As a fluoride anion is monovalent and the smallest in its size among different kinds of anions, it is expected to be mobile in solids. Fluorite (CaF_2) is a typical fluorite-type structure of f.c.c. and the array of anions is somewhat coarse. As already shown in Fig. 1, the fluoride ion conductivity of PbF_2 is $3 \times 10^{-6} \text{ S cm}^{-1}$ at 600K and increases up to $10^{-4} \text{ S cm}^{-1}$ at 800°C , where some (5 ~ 10%)

Fig. 10 Conductivity of fluoride ion conductors.

Table 8 Typical fluoride ion conductors

Material	Conductivity ($S\text{ cm}^{-1}$)	Note
$\text{Ca}_{0.894}\text{U}_{0.091}\text{Ce}_{0.005}\text{F}_{2.187}$	8×10^{-3} (150°C)	Fluoride
$\text{Pb}_{0.45}\text{Bi}_{0.25}\text{F}_{2.25}$	6×10^{-3} (150°C)	
PbSnF_4	8×10^{-2} (150°C)	
$\text{Ce}_{0.95}\text{Ca}_{0.05}\text{F}_{2.95}$	6×10^{-3} (150°C)	Tysonite
$(\text{ZrF}_4)_{0.50}(\text{BaF}_2)_{0.35}(\text{CsF})_{0.15}$	3×10^{-6} (150°C)	Glass
$(\text{InF}_3)_{0.35}(\text{SnF}_2)_{0.30}(\text{PbF}_2)_{0.35}$	8×10^{-4} (150°C)	

fluoride anions distribute in interstitial sites and generate fluoride ion vacancies which cause the high fluoride ion conductivity at high temperature.

A doping of lower valent cations for calcium sites creates anion vacancies, which allows fluoride anions to migrate in the crystal. The solid solution $(\text{CaF}_2)_{0.95}(\text{NaF})_{0.05}$ is an example. In fact, there are many kinds of fluoride ion conductors. They are roughly classified into three categories, ie, fluorite-type, PbCl_2 -type, and tysonite-type. Among the fluoride ion conductors, PbSnF_4 , whose crystal structure is a fluorite-related type, shows the highest conductivity as shown in Fig. 10. Since the tysonite-type LaF_3 is chemically stable with moderate conductivity, it is used as a selective electrode for fluoride ion sensors. Some fluoride glasses as $(\text{InF}_3)_{0.35}(\text{SnF}_2)_{0.4}(\text{PbF}_2)_{0.35}$ has also high conductivity around 10^{-3} S cm^{-1} at 150°C. Typical fluoride conductors are listed in Table 8.

As chloride ions are larger in size than fluoride ions, oxide ions and most of cations of the metallic elements, it is difficult for them to migrate easily in solids. However, some chloride ion conductors are known although their conductivity is low; for example, $(\text{PbCl}_2)_{0.97}(\text{KCl})_{0.33}$ shows $3 \times 10^{-3}\text{ S cm}^{-1}$ at 300°C. Doped SnCl_2 shows also high chloride conductivity but is chemically unstable in the atmosphere. It has been reported that the perovskite-type chloride CsPbCl_3 exhibits chloride ion conduction of $1 \times 10^{-3}\text{ S cm}^{-1}$ at 500°C.

Oxide Ion Conductors

Similar to the fluoride ion conductors, rather small size oxide anion O^{2-} is often mobile in some solid oxides at elevated temperatures. Many kinds of oxide-ion conductors are known and are classified into several types (Tables 9 and 10). A series of defect fluorite-type oxides which have an appreciable amount of oxide ion vacancy is the most familiar. The host oxides are tetravalent oxides MO_2 or trivalent oxides (sesqui-oxides) M_2O_3 ; typical example of the former is stabilized zirconia, in which trivalent or divalent cations are partially substituted for tetravalent zirconium in ZrO_2 . Thus, oxide ion vacancies are formed as a

Table 9 Classification of oxide-ion conductors

Crystal type	Host oxide	Example
Fluoride-type		
MO ₂ -based	ZrO ₂ CeO ₂ ThO ₂	(ZrO ₂) _{0.92} (Y ₂ O ₃) _{0.08} (ZrO ₂) _{0.8} (Sm ₂ O ₃) _{0.2} (ThO) _{0.9} (CaO) _{0.1}

Scheelite-type	PbWO ₄	Pb _{0.8} La _{0.2} WO _{4.1}

Fig. 11 Mechanism of oxide ion conduction in stabilized zirconia.

result of charge compensation as shown in Fig. 11. At elevated temperatures of several hundred degree Celsius, oxide ions can easily move with the help of the vacancies and give rise to the high oxide ion conductivity. A representative ceramic is yttria-stabilized zirconia (YSZ), the typical composition of which is (ZrO₂)_{0.92}(Y₂O₃)_{0.08} (8Y). This ceramic is very popular and widely used in many fields because the conductivity is fairly good and cheap in cost. Magnesium-doped zirconia is often used because of its good resistance to thermal shock and calcium-doped zirconia because of low cost, although the conductivity is not as high as that of YSZ.

Ceria-based solid solutions composed of (CeO₂)_{1- x} (M₂O₃) _{x} are also oxide ion conductors of this class and the conductivity is, in general, higher than that of zirconias, although they are not so strong against a reducing atmosphere at high temperature as

Fig. 12 Temperature dependence of conductivity of lithium ion (Kamaya *et al.*, 2011).

zirconia. The solid solutions based on thorium such as $(\text{ThO}_2)_{0.9}(\text{CaO})_{0.1}$ are oxide ion conductors although they are accompanied by hole conduction under an oxidizing atmosphere.

The conductivity of pure $\alpha\text{-Bi}_2\text{O}_3$ (below 730°C) is low and electronic. However, it is transformed above 730°C to $\delta\text{-Bi}_2\text{O}_3$ which belongs to the defect fluorite-type structure and this phase exhibits very high oxide ion conductivity as shown in Fig. 12. This high conductivity phase can be stabilized by substituting tri-, penta-, or hexavalent cations partially for bismuth; for example, $(\text{Bi}_2\text{O}_3)_{0.73}(\text{Y}_2\text{O}_3)_{0.27}$, $(\text{Bi}_2\text{O}_3)_{0.85}(\text{Nb}_2\text{O}_5)_{0.15}$, and $(\text{Bi}_2\text{O}_3)_{0.75}(\text{WO}_3)_{0.25}$, which exhibit high conductivity at around 500°C . However, they are not available for practical use since they are easily reduced under a reducing atmosphere at elevated temperatures. $\text{Na}_{0.5}\text{Bi}_{0.5}\text{TiO}_3$.

Another category of oxide ion conductors is a series of *perovskite-type oxides* which have oxide ion vacancies in their lattice. The oxide ion vacancies are created by partial substitution of lower valent cations for host cations. One example is $\text{CaTi}_{0.7}\text{Al}_{0.3}\text{O}_{2.85}$ in which the tetravalent titanium in CaTiO_3 is partially replaced by trivalent aluminum to create oxygen vacancies, whose conductivity is as high as that of calcia-stabilized zirconia although it contains some electronic conduction under an oxidizing atmosphere at high temperature. Among the perovskite-type oxides, the LaGaO_3 -based oxides such as $\text{La}_{0.8}\text{Sr}_{0.2}\text{Ga}_{0.8}\text{Mg}_{0.2}\text{O}_3$ and $\text{La}_{0.8}\text{Sr}_{0.2}\text{Ga}_{0.8}\text{Mg}_{0.115}\text{Co}_{0.085}\text{O}_3$ have very high oxide ion conductivity at around 600°C where next generation SOFC is expected to operate. The high-temperature phase (above 950°C) of brownmillerite $\text{Ba}_2\text{In}_2\text{O}_5$ is also a typical example, in which one sixth of the oxygen in the normal perovskite structure is deficient. This high conductivity phase can be stabilized by substituting cerium or zirconium partially for indium. Scheelite-type oxides such as PbWO_4 have been reported to exhibit oxide ion conduction with moderate conductivity.

Mixed Ionic-Electronic Conductors

The charge carrier in a solid electrolyte is typically one kind of ions of which the solid is composed. Stabilized zirconia, Na β -alumina and RbAg_4I_5 under normal condition are regarded as pure ionic conductors of oxide ions, sodium ions, and silver ions, respectively. However, some solids show both ionic and electronic conduction and sometimes the electronic conductivity σ_e is much higher than the ionic conductivity σ_i although the ionic conductivity itself is markedly high. These solids are called *mixed ionic-electronic conductors* (MIEC) or simply *mixed conductors*. The mixed conduction is often attributed to a nonstoichiometry of the compound especially in case of ionic crystals as oxides, sulfides and halides, where not only ionic defects but also electronic defects such as excess electrons e^- or holes h^+ can be generated by the nonstoichiometry. However, it is worth noted that even in a metallic solid like LiIn alloy, the lithium (ion) is fast diffusing, which can be categorized in MIEC also.

Silver chalcogenides such as $\text{Ag}_{1+\delta}\text{S}$ and $\text{Ag}_{1+\delta}\text{Se}$ seem outwardly to be n type electronic conductors. However, Ag^+ ion conductivity of these solids at elevated temperatures ($> 200^\circ\text{C}$) is in the order of 1 S cm^{-1} which is comparable to that of $\alpha\text{-AgI}$ at the same temperature range. The electronic conductivity is a few orders of magnitudes higher than the ionic one depending on the composition. Cu_2S is another example of a chalcogenide mixed conductor. This material shows Cu^+ ion conduction as well as p type electronic (hole) conduction.

Some insertion compounds can be put into this category; for example, Li_xCoO_2 , $\text{Li}_x\text{Mn}_2\text{O}_4$, Li_xTiS_2 , etc., are known as the cathode materials for lithium ion batteries, which have both electronic (hole) and lithium ionic conductivities. Also, in the anode

Fig. 13 Conductivity of typical oxide ion conductors (Sasaki, 2013).

(negative electrode) materials as Li_xC and alloys as Li_xIn , Li_xSn , Li_xSi , Li_xAl , Li_xMg , etc., are thought of electronic and lithium ion conductors. Another interesting example is $\beta\text{-Mg}_3\text{Bi}_2$, which has large diffusivity of Mg since the sublattice of small Mg is melting among the fixed Bi sublattice like $\alpha\text{-AgI}$ (Barnes *et al.*, 1994). H_xWO_3 which is used for electrochromic devices has large hydrogen mobility as well as high electronic conductivity.

Most important application of the ion-electron mixed conductors is the Solid Oxide Fuel Cells (SOFC), which works in very high temperature up to 800 to 1000°C where no metallic electrode is stable. Thus, the electronic conduction of oxide ceramics are used for the electrode materials, which have also the conductivity of oxide ions (Fig. 12). As was shown above, some oxide ion conductors have electronic (hole) conductivity under reduced or oxidative atmosphere, which is a drawback for the electrolyte but is useful for the electrodes.

Ceria-based oxide ion conductors as $(\text{CeO}_2)_{0.8}(\text{Sm}_2\text{O}_3)_{0.2}$ and $(\text{CeO}_2)_{0.8}(\text{Gd}_2\text{O}_3)_{0.2}$ become partially electronic conductors under a reducing atmosphere at high temperatures, where the ceria electrolytes are partially reduced and nonstoichiometric oxygen defects are formed with excess electrons which contribute to the electronic conduction. In general, the electronic conductivity of an oxide electrolyte at elevated temperatures is influenced by partial oxygen pressure ($p\text{O}_2$) surrounding them. The n type electronic conductivity σ_n increases with decreasing $p\text{O}_2$, whereas p type electronic conductivity σ_p increases with increase in $p\text{O}_2$. It is known that the relations between σ_n or σ_p and $p\text{O}_2$ are given by

$$\sigma_n = \sigma_n^0 \exp p\text{O}_2^{-1/n} \quad (9)$$

and

$$\sigma_p = \sigma_p^0 \exp p\text{O}_2^{1/n} \quad (10)$$

where n is a natural number, and σ_n^0 and σ_p^0 are constants which are independent of the partial pressure of oxygen. It is accepted that the ionic conductivity σ_i itself is rarely dependent on $p\text{O}_2$ for many oxide electrolytes. Accordingly, the total conductivity σ is expressed as,

$$\sigma = \sigma_i + \sigma_n^0 \exp p\text{O}_2^{-1/n} + \sigma_p^0 \exp p\text{O}_2^{1/n} \quad (11)$$

The relation between the logarithm of conductivity and logarithm of $p\text{O}_2$ is illustrated in Fig. 13. The hatched regions indicate the mixed conduction domains, and between them there exists an ionic conduction domain where the electronic conductivity is negligibly small. The outer sides of the mixed conduction domains are electronic conduction regions.

Some perovskite-type oxides containing transition elements exhibit mixed conduction at elevated temperatures. Doped-lanthanum cobaltites are mixed conductors in which oxide ions and holes are the charge carriers. The electronic conductivity is a few orders of magnitudes higher than that of the oxide ionic, although the ionic conductivity itself is sufficiently high ($> 1 \times 10^{-1} \text{ S cm}^{-1}$). High temperature-type protonic conductors based on, for example, SrCeO_3 and BaCeO_3 are a kind of mixed conductor under humidified air at high temperature. In this case, the charge carriers are both protons and electron holes.

Fig. 14 Dependence of conductivity on oxygen partial pressure in the case of mixed conducting oxides.

Applications of Ion Conducting Solids

Benefits of Ion Conducting Solids for Applications

Ion conducting solids, ie, solid-state ionics materials are classified as solid electrolytes and mixed conductors, both of which have peculiar functions applicable in the field of advanced technologies. A solid electrolyte is a functional material in which mobile ions play an important role. In general, solid electrolytes have the following benefits:

- (i) They have both an electrical and a chemical function.
- (ii) They can serve both as ionic and structural materials.

With regards to point (ii) a solid electrolyte has a dual function, ie, it acts both as a structural material and as an ion conductor. In this sense, solid electrolytes are convenient compared to ion conducting liquids which need a container. With regard to (i) these materials conduct electricity while they simultaneously give rise to some chemical reactions at the surface of the electrolyte. Inversely, when different chemical reactions take place at both sides of the solid electrolyte surfaces, an electromotive force (EMF) is generated across the electrolyte.

Three Fundamental Functions Applicable to Devices

Ion conducting solid has the following three essential functions applicable to many electrochemical devices, ie, appearance of electromotive force, preferential permeation of a specific ion, and formation of large space charge.

An EMF is caused when a difference in concentration (or activity) of a specified chemical component is generated between the two sides of an ion conducting solid diaphragm. **Fig. 14** illustrates this phenomenon for the case of an oxide ion conductor. In this oxygen concentration cell the EMF, E , is given by

$$E = \frac{RT}{4F} \ln \frac{pO_2(1)}{pO_2(2)} \quad (12)$$

where $pO_2(1)$ and $pO_2(2)$ are the oxygen partial pressures in electrode compartment (1) and (2), respectively. This EMF phenomenon can be applied to chemical sensors and power cells (**Fig. 15**).

Fig. 16 shows a schematic illustration of the preferential permeation of oxygen in the case of an oxide ion conductor as an example. This function is based on a property that only one kind of ion can move in a solid electrolyte. Using this function, one can extract a specified element from a mixture or a molecule. This can be applied to the electrolysis of molecules and separation of specified gas from gas mixture. Formation of large space charge is caused by uneven distribution of mobile ions after an electric field was applied.

Application Examples

There are many possible applications of ion conducting solids. First group is chemical sensors; for example, oxygen gas sensors for automobile engine control or steel making, NO_x sensors and cleaner for exorsts gas controle, CO_2 sensors. Second group is

Fig. 15 EMF of oxygen concentration cell.

Fig. 16 Oxygen purification by oxide ion conductor.

electrochemical energy sources such as lithium ion battery, NaS battery and various fuel cells. Third kind is for ion transfer membrane for gas purification, electrochemical reactors. Fourth kind is for electronic devices as electrochromic display, or atom-switch etc. Some of them are depicted below.

(a) Sensors

The appearance of an EMF across a solid electrolyte is based on the principle of an electrochemical cell or battery. The batteries for practical use are classified into "signal" cell and "power" cell. The signal cell is used as a sensor for measuring the concentration of a specified material. For example, with regards to oxygen, if $p_{O_2}(1)$ in Eq. (12) is known and is constant, the partial pressure of oxygen in compartment (2) can be determined from the EMF of the cell and this functions as an oxygen sensor. Oxygen sensors using stabilized zirconia as an oxide ion conductor are now widely used for the analysis of exhaust gases from engines, industrial furnaces, respiration, etc. This sensor works at temperatures higher than 400°C . At lower temperatures the electrode polarization and ohmic resistance are too large to give an exact EMF of the cell. They are also used to probe the oxygen activity in molten iron in the steel making process. Besides the oxygen sensors, a fluoride ion sensor using fluoride ion-conducting solid LaF_3 and a sodium sensor using $\text{Na } \beta\text{-alumina}$ are in practical use. A hydrogen sensor for molten aluminum in industrial casting processes has been developed using the proton conducting ceramic of $\text{CaZr}_{0.9}\text{In}_{0.1}\text{O}_{3-x}$. SO_x and NO_x sensors using sodium ion conductor or oxide ion conductors with sulfates or nitrates as auxiliary materials are developed.

Fig. 17 Concept of all-solid-state thin-film lithium battery (Bates *et al.*, 2000).

(b) Lithium ion batteries

After the invention of rechargeable Lithium Ion Batteries (LIB) in 1980, they have been used in mobile phone, PC, tablet, etc., for IT devices and now for plug-in-hybrid (PHV) and electric vehicles (EV). For this purpose, the lithium ion transport in solids, liquid, polymer and gels has been widely investigated. A conventional lithium ion battery consists of lithium transition metal oxide (eg, LiCoO_2 , LiMn_2O_4 , LiFePO_4 , etc.) for cathode, lithium carbon (Li_xC) or lithium alloys (Li_xSn , Li_xSi , etc.) for anode, and organic liquid electrolyte ($\text{EC} + \text{DMC} + \text{LiPF}_6$, etc.). Those cathode and anode materials are considered as ion-electron mixed conductors as shown in the section on Mixed Ionic-Electronic Conductors, although whose ionic conductivity is much smaller than the electronic one.

If the liquid electrolyte of the LIB is replaced by a solid electrolyte, an all-solid state lithium battery can be constructed, which has a big merit on safety and long life stability. For this purpose, sulfide based solid electrolytes such as $\text{Li}_{10}\text{GeP}_2\text{S}_{12}$ and similar glasses are developed as the first candidate since its conductivity is as high as conventional liquid electrolytes. However, it is rather unstable against the contact to lithium metal and water. Oxide based solid electrolytes such as LIPON, LLZ etc., are the other candidates, which are stable to lithium metal although the conductivity is lower than the sulfides. In order to reduce the resistance of the solid electrolyte, thin film technology is developed to construct all-solid-state thin-film batteries (TFB), in which the electrolyte thickness is $1\text{ }\mu\text{m}$ or less and the total thickness is less than $100\text{ }\mu\text{m}$ (see Fig. 17). In spite of the small capacity of the TFB it is now recognized very suitable for micro wearable or implant devices as well as energy harvesting applications.

(c) NaS battery

Because of the larger natural abundance of sodium than lithium, many studies are under going to construct large scale sodium batteries for mega watt (MW) class. The principle of the sodium battery is similar to that of lithium, however the higher reactivity of sodium hampered the development. Only so called NaS battery is commercially available at present. The working principle of a NaS battery is shown in Fig. 18. A single cell is made of a $\text{Na}\beta''$ -alumina ceramic tube containing liquid sodium metal and surrounded by molten sulfur. The cell is sealed in a stainless steel tube working as a current collector. The cell is working above 300°C to keep the sodium and sulfur in molten state. Single cell voltage is 1.8 V and the capacity of 1220 Wh, which is assembled to 384 cells of 400 kWh. Farther assembling them to construct large scale energy storage system up to 50 MW is developed by NGK Insulators, LTD, Japan, which is now widely used for back-up system and load leveling of wind and solar energies.

(d) Solid oxide fuel cell (SOFC)

The principle of the SOFC is shown in Fig. 19, where the hydrogen gas reacts with oxide ions in solid electrolyte (eg, YSZ) to produce water and electricity. This type of power generator is, in principle, very high in efficiency, clean in exhaust gas, and silent to run. Siemens-Westinghouse Co. have developed 100 kW-scale SOFC. IX and Tokyo Gas have sold s SOFC of max. 700 W for home stationary use, which is equipped with reforming system of natural gas to hydrogen and cogeneration system to use the exhost heat for hot water supply.

(e) Electrolysis of gaseous molecules

If a fuel cell is operated inversely, hydrogen is obtained from steam; for example, polymer electrolyte type PEM electrolyzer and solid oxide electrolyzer cell (SOEC) are known. This method is a promising way to produce hydrogen effectively in large scale, and will be a powerful tool for the future age of hydrogen economy, however the efficiency and cost are still the neck for practical use. Steam electrolysis is also possible using proton conducting ceramics. In this case pure hydrogen free from water vapor is obtained.

(f) Gas separation

By using oxide ion conductors or proton conductors, pure oxygen or hydrogen gas can be obtained in a one-step operation as shown in Fig. 16. Electrochemical oxygen pumps made of stabilized zirconia are on the market. This device can pump up or add oxygen gas preferentially from or to a gas mixture and is utilized in many laboratories. A hydrogen pump which uses proton-conducting ceramics is in development.

Fig. 18 Concept and structure of NaS battery.

Fig. 19 Concept of solid oxide fuel cell (SOFC).

Fig. 20 Principle of atomic switch (Aono and Hasegawa, 2010).

(g) Atomic switch or nano-ionics circuits

Electrochemical deposition of metals from solid electrolyte is common phenomena in solid state ionics, however whose nano-scale control is now open the door to new electric circuit technology called "Atomic Switch" (Aono and Hasegawa, 2010), "Nanoionics switch" (Wase and Aono, 2007). The principle is shown in Fig. 20, where Ag metal wire works as a source of silver ions and Pt metal is

Fig. 21 An example of nano-ionics switch architecture (Wase and Aono, 2007).

the collector of deposited silver metal filament. Ag_2S is an ionic-electronic mixed conductor which works as a transfer channel of silver ions and also electronic current conductor when the switch is on. When the top Ag electrode is positively biased and Pt is negative, a potential difference appears on the gap between the Pt and Ag_2S , which generates the accumulation of silver ions in the Ag_2S and finally the oversaturated silver metals start to form a small needle at the bottom of the Ag_2S . The needle finally contacts to the Pt electrode and the both electrodes are short circuited. When the potential bias is reversed, the precipitated silver needle between the Ag_2S and Pt is absorbed into the Ag_2S and the circuit is now open. Starting from this principle, many circuit designs are now proposed. A prototype device design is shown in Fig. 21. These phenomena are reversible in nano-scale and is used for a memory device, switching device, synaptic switch etc. For this purpose, not only the Ag_2S but many ionic conductors and mixed conductors have been tested now.

Introduction

Since their commercialization in the 1990s, lithium-ion secondary batteries (LIBs) have been widely used in mobile phones, personal computers, automobiles, and aircraft as high-voltage and high-energy-density batteries, thus contributing to our daily lives. Recently, the research and development of all-solid-state batteries have been accelerating to further improve the safety and performance of LIBs. For all-solid-state batteries, the risk of liquid leakage and ignition can be suppressed by replacing the conventionally used organic electrolyte with a flame-retardant inorganic solid electrolyte, increasing their safety and reliability. All-solid-state batteries are mainly classified into two types: thin-film and bulk types. The thin film type is fabricated by laminating electrode active materials, then solid electrolytes are formed by sputtering or vapor deposition, while the bulk type is fabricated by laminating layers of different powders. The bulk type is suitable for large batteries because the capacity can be increased by increasing the amount of the electrode active material powder.

In a bulk type, a mixture of electrode active material, solid electrolyte, and conductive additive powders are used as a composite electrode. To realize a uniform electrode reaction in the electrode layer, it is key to form a path for the continuous conduction of sufficient ions or/and electrons to the active material. For this reason, research and development on bulk-type all-solid-state batteries have focused on the following two points:

- (1) Finding a solid electrolyte with a high ionic conductivity.
- (2) How to build an excellent solid–solid interface between electrode active materials and solid electrolytes.

This chapter first introduces the development of sulfide solid electrolytes with a high lithium ion conductivity. After that, the structures of typical sulfide glasses under several conditions are described. Finally, results obtaining by the authors for the mechanical properties of sulfide solid electrolytes that are advantageous for forming a solid–solid interface are given.

Crystalline Solid Electrolytes

Typical sulfide solid electrolytes that have been developed so far are summarized in [Table 1](#). Sulfide solid electrolytes are mainly classified into three types: crystal, glassy, and glass ceramic. A series of sulfide crystals called thio-LISICON was developed in the 2000s, and $\text{Li}_{3.25}\text{Ge}_{0.25}\text{P}_{0.75}\text{S}_4$ of the Li_4GeS_4 – Li_3PS_4 series was reported to have a high lithium ionic conductivity of $2.2 \times 10^{-3} \text{ S cm}^{-1}$ at room temperature ([Kanno and Murayama, 2001](#)). These sulfide crystals have low ionic conductivities of $10^{-7} \text{ S cm}^{-1}$ or less for simple compositions such as Li_4GeS_4 and Li_4SiS_4 , but the substitution of Ge^{4+} or Si^{4+} to Al^{3+} or P^{5+} increases the lithium ionic conductivity. In 2010, the sulfide crystal $\text{Li}_{10}\text{GeP}_2\text{S}_{12}$ (LGPS) with a very high ionic conductivity on the order of $10^{-2} \text{ S cm}^{-1}$ was found ([Bron et al., 2013](#); [Kamaya et al., 2011](#)). Then, the sulfide crystal $\text{Li}_{9.54}\text{SiP}_{1.44}\text{S}_{11.7}\text{Cl}_{0.3}$ with the highest ever reported ionic conductivity of $2.5 \times 10^{-2} \text{ S cm}^{-1}$ was discovered in 2016 ([Kato et al., 2016](#)). An all-solid-state battery using this crystal as a solid electrolyte has an extremely high charge and discharge of 1500C at 100°C. On the other hand, Ge- and Si-containing systems have problems with the stability of highly reducible negative electrodes such as lithium metal. As systems that do not contain Ge or Si, $\text{Li}_{9.6}\text{P}_3\text{S}_{12}$ ([Bron et al., 2013](#)) of the LGPS type and $\text{Li}_6\text{PS}_5\text{X}$ ($\text{X} = \text{Cl}, \text{Br}$) ([Boulinau et al., 2012](#)) of the argyrodite type were discovered, which have high ionic conductivities of $10^{-3} \text{ S cm}^{-1}$. These sulfide crystals are usually produced by a solid-phase synthesis in which raw powders are mixed and then heated at a high temperature of 400–700°C. Yubuchi et al. reported that an argyrodite-type sulfide crystal can be synthesized in a liquid phase in a mixed solvent of THF and ethanol ([Yubuchi et al., 2019](#)). Since the argyrodite crystals are dissolved in the solvent, argyrodite solid electrolytes can be deposited so as to cover the electrode active material particles, and a wide contact interface can be formed between the electrode active material and the solid electrolyte.

Glassy and Glass-ceramic Solid Electrolytes

Prior to the development of the above-mentioned crystalline sulfide solid electrolytes, Li_2S – P_2S_5 – LiI ([Mercier et al., 1981](#)) and Li_2S – B_2S_3 – LiI ([Wada et al., 1983](#)) glassy electrolytes exhibiting a conductivity of about $10^{-3} \text{ S cm}^{-1}$ were reported in the 1980s. A melt-quench method is generally used to synthesize amorphous materials such as glasses. The authors and others prepared that oxy-sulfide glasses with various lithium ortho-oxo acids of the form Li_xMO_y ($\text{Li}_x\text{MO}_y = \text{Li}_4\text{SiO}_4, \text{Li}_3\text{PO}_4$) added to the Li_2S – SiS_2 system by the melting method ([Aotani et al., 1994](#); [Minami et al., 2006](#)). In both glasses, a high ionic conductivity of $10^{-3} \text{ S cm}^{-1}$ was exhibited when a small amount (5 mol%) of lithium ortho-oxo acid was added. On the other hand, a mechanochemical

method has been developed for forming an amorphous material (Hayashi *et al.*, 2001; Hayashi *et al.*, 2016), in which high-speed planetary ball mills are used to mechanically crush and grind raw materials to induce a chemical reaction. This method enables the production of glass at ordinary temperatures and ordinary pressure. Since the composite is a fine powder, it can be easily used for bulk-type all-solid-state batteries. Furthermore, although the Li_2S content of the glass obtained by the melt quenching method was only up to 70 mol%, the Li_2S content in the Li_2S – P_2S_5 system was increased to 75 mol% by using the mechanochemical method (Hayashi *et al.*, 2001). Moreover, it was found that a glass ceramic with a Li_2S content of 80 mol% was precipitated by heat-treating the glass above the crystallization temperature, which is similar to the LGPS-type phase and has a high ionic conductivity of 10^{-3} S cm^{-1} (Mizuno *et al.*, 2006). A glass-ceramic phase having a Li_2S content of 70 mol% obtained by heating and crystallizing a glass exhibited a high ionic conductivity of 10^{-2} S cm^{-1} (Seino *et al.*, 2014). Furthermore, it has been found that a sulfide glass having a Li_2S content of 75 mol% exhibits a high ionic conductivity if it is heated at a high temperature before crystallization (Shiotani *et al.*, 2017).

Structure for Li_2S – P_2S_5 Glassy System (Ohara *et al.*, 2016)

The lithium ionic conductivity of $67\text{Li}_2\text{S} \cdot 33\text{P}_2\text{S}_5$ ($67\text{Li}_2\text{S}$), $70\text{Li}_2\text{S} \cdot 30\text{P}_2\text{S}_5$ ($70\text{Li}_2\text{S}$), and $75\text{Li}_2\text{S} \cdot 25\text{P}_2\text{S}_5$ ($75\text{Li}_2\text{S}$) glasses are 5.6×10^{-5} , 1.4×10^{-4} , and $3.0 \times 10^{-4}\text{ S cm}^{-1}$, respectively. The bulk structure and the environment of the Li^+ ions were studied by structural analysis combining X-ray and neutron diffraction with the aid of density functional theory (DFT)/reverse Monte Carlo (RMC) simulation and Raman spectroscopy to reveal the relationship between structural properties and lithium ionic conductivity.

To quantitatively evaluate the fraction of PS_x polyhedral anions, the Raman spectra of $67\text{Li}_2\text{S}$, $70\text{Li}_2\text{S}$, and $75\text{Li}_2\text{S}$ glasses were obtained, as shown in Fig. 1(a). Bands in the frequency range of 330 – 480 cm^{-1} are sensitive to the S–P–S bond angle. On the basis of previous studies (Mizuno *et al.*, 2005; Tachez *et al.*, 1984), we assigned the three bands at approximately 425 , 410 , and 390 cm^{-1} to the stretching vibration of the $\text{P}_2\text{S}_6^{3-}$ (ortho-thiophosphate) ion, $\text{P}_2\text{S}_7^{4-}$ (pyro-thiophosphate) ion, and $\text{P}_2\text{S}_6^{4-}$ (an ethane like structure with a P–P bond) ion, respectively. Since the scattering coefficient in Raman spectroscopy is affected by the PS_x polyhedral anion (Iwamoto *et al.*, 1987; Umesaki *et al.*, 1993), the ratios of the $\text{P}_2\text{S}_6^{3-}$, $\text{P}_2\text{S}_7^{4-}$, and $\text{P}_2\text{S}_6^{4-}$ ions were estimated by a Lorentzian function, shown as dotted lines in Fig. 1(b), and are summarized as open circles, open triangles, and open squares in Fig. 1(c), respectively. It is clear that the ratio of $\text{P}_2\text{S}_6^{3-}$ ions increases with the Li_2S content, while the ratios of $\text{P}_2\text{S}_7^{4-}$ and $\text{P}_2\text{S}_6^{4-}$ ions decrease. This tendency is in good agreement with that observed in previous studies (Hayashi *et al.*, 2010a,b; Mizuno *et al.*, 2005). Furthermore, the band corresponding to the stretching vibration of the P–P bond also disappears at approximately 530 cm^{-1} for the $75\text{Li}_2\text{S}$ glass, as shown in the inset of Fig. 1(a). Since the band at 547 cm^{-1} for polycrystalline $\text{Li}_4\text{P}_2\text{S}_6$ is characterized by the stretching vibration of the P–P bonds (Mercier *et al.*, 1982), the bands observed at 530 cm^{-1} in the glasses are related to the P–P stretching vibration. The disappearance of this band is consistent with the decrease in the ratio of $\text{P}_2\text{S}_6^{4-}$ ions. Intriguingly, it was found that $\text{P}_2\text{S}_6^{4-}$ ions exist in these glasses with ratios of approximately 33.0%, 18.3%, and 4.4% in $67\text{Li}_2\text{S}$, $70\text{Li}_2\text{S}$, and $75\text{Li}_2\text{S}$, respectively, whereas they should not be contained in the stoichiometric compositions ($0\text{PS}_4:100\text{P}_2\text{S}_7$ in $67\text{Li}_2\text{S}$, $50\text{PS}_4:50\text{P}_2\text{S}_7$ in $70\text{Li}_2\text{S}$, and $100\text{PS}_4:0\text{P}_2\text{S}_7$ in $75\text{Li}_2\text{S}$). This means that there is a sulfur deficiency in these glasses. The sulfur deficiency is consistent with the result of an inductively coupled plasma analysis. Hayashi *et al.* (2010b) found by NMR measurement that a small number of $\text{P}_2\text{S}_6^{4-}$ ions are formed in the glass ceramic $70\text{Li}_2\text{S} \cdot 28\text{P}_2\text{S}_5 \cdot 2\text{P}_2\text{S}_3$, and the degradation of conductivity is expected to be caused by the formation of $\text{P}_2\text{S}_6^{4-}$ ions.

To extract quantitative information on the atomic arrangements in the glassy materials from the diffraction data, the total correlation functions $4\pi r\rho_0 g(r)$, where ρ_0 is the average atom number density and $g(r)$ is the pair distribution function, were

Fig. 1 (a) Raman spectra in the range of 330–480 cm⁻¹ for Li₂S–P₂S₅ glasses. Black, blue, and green lines represent 75Li₂S, 70Li₂S, and 67Li₂S glasses, respectively. The spectra in the range of 400–560 cm⁻¹ are enlarged in the inset for clarity. (b) Spectral decomposition of Raman spectrum for 70Li₂S glass. Blue line, experimental data; dotted lines, fitting results for all PS polyhedra (light-blue), and PS₄ (black), P₂S₇ (red), and P₂S₆ (blue) anions. (c) PS_x polyhedral fractions for Li₂S–P₂S₅ glasses derived from Raman spectra (open marks) and DFT/RMC model (filled marks).

Fig. 2 Total correlation functions $4\pi r \rho_0 g(r)$ for 75Li₂S glasses derived from X-ray (solid line) and neutron (dotted line) diffraction results.

calculated for each glass by Fourier transformation of the X-ray and neutron diffraction data (Keen, 2001). Fig. 2 shows $4\pi r \rho_0 g(r)$ for 75Li₂S glass. From the negative coherent scattering length of neutrons for ⁷Li (hereafter the superscript is omitted), it is possible to identify the P–S and Li–S correlation lengths. The first peak at approximately 2.0 Å in both sets of diffraction data is related to the P–S correlation associated with the PS₄ tetrahedral anions, while the second negative peak at approximately 2.5 Å is related to the Li–S correlation length. Both lengths are similar for all compositions and hence do not provide any specific information to help identify the structural features.

To uncover the relationship between the glassy structure and the high ionic conductivity for these glasses, the authors modeled the atomic structure of the Li₂S–P₂S₅ glasses by DFT/RMC simulation using X-ray and neutron diffraction data, fixing the ratios of the PS₄³⁻, P₂S₇⁴⁻, and P₂S₆⁴⁻ ions on the basis of Raman spectroscopy measurements to reproduce the plausible glassy structures. The DFT/RMC model is consistent with the experimental data.

To obtain information on the partial correlation in real space, the partial pair distribution functions (PDFs), $g_{ij}(r)$, for the Li₂S–P₂S₅ glasses were calculated from the DFT/RMC model. $g_{ij}(r)$ for P–S correlation, $g_{P-S}(r)$, has a peak at approximately $r = 2.0$ Å and a shoulder on the high- r side. This bond length is consistent with that of a bridging sulfur (BS) in a P–S–P bond. $g_{Li-S}(r)$ also has a peak at approximately $r = 2.5$ Å, which is consistent with the experimental results for the PDF. Furthermore, $g_{P-P}(r)$ has two peaks at $r = 2.2$ Å and $r = 3.5$ Å, corresponding to the bond length of the P₂S₆⁴⁻ ion and the correlation length of the P₂S₇⁴⁻ ion, respectively. All the $g_{ij}(r)$ peaks except for that of Li–Li are well defined and sharp because the combination of X-ray diffraction, neutron diffraction, and DFT calculation provides us with a sufficient number of factors for each correlation. Note that the difference between the three glasses is very small, suggesting that their atomic correlations are very similar.

Table 2 N_{i-j} : Partial coordination number of j atoms around i atoms

Samples	67Li ₂ S glass	70Li ₂ S glass	75Li ₂ S glass
N_{P-Li}	2.04	2.20	3.23
N_{P-P}	0.36	0.13	0.09
N_{P-S}	3.64	3.87	3.92
N_{Li-Li}	0.55	0.66	0.79
N_{Li-P}	0.98	0.94	1.11
N_{Li-S}	4.74	4.57	4.58
N_{S-Li}	2.93	2.96	3.41
N_{S-P}	1.09	1.07	1.00
N_{S-S}	0.40	0.28	0.21

Fig. 3 (a) Comparison between P-centered (open marks with dotted line) and Li-centered Voronoi polyhedra (filled marks with solid line) for Li₂S–P₂S₅ glasses derived from DFT/RMC model. (b) Polyhedral connection statistics for Li₂S–P₂S₅ glasses calculated using DFT/RMC model. All connections are between PS_x and LiS_y polyhedra. Red, green, and blue represent PS₄^{3–}, P₂S₇^{4–}, and P₂S₆^{4–} ions, respectively. Filled and hatched bars represent corner and edge sharing, respectively.

To understand the short-range correlation in detail, the coordination numbers in the Li₂S–P₂S₅ glasses calculated up to 3.2 Å are summarized in Table 2. The coordination number of S around P, N_{P-S} , increases with increasing Li₂S content owing to the disappearance of the P₂S₆^{4–} ions. N_{P-Li} also increases, while N_{Li-P} and N_{Li-S} remain almost constant in the three compositions.

To obtain the coordination environment of the Li⁺ ions in detail, Voronoi polyhedron statistics were calculated by Voronoi tessellation analysis (Borodin, 1999; Finney, 1970), in which the coordination is assigned by a Voronoi index $\langle n_3, n_4, n_5, n_6 \rangle$, where n_i denotes the number of i -edged faces and $\sum_i n_i$ is the total coordination number. The results for Li-centered Voronoi polyhedra calculated up to 3.2 Å are shown in Fig. 3(a), together with results for P-centered polyhedra. This length of 3.2 Å corresponds to the first coordination length of the Li–S correlation determined by the DFT/RMC model. Therefore, the calculation of P-centered Voronoi polyhedra includes information about the coordination environment beyond the first coordination length of P–S correlation. The P-centered Voronoi polyhedra up to the first coordination environment have no composition dependence. It is clear that the fractions of $\langle 2\ 3\ 0\ 0 \rangle$ and $\langle 2\ 2\ 2\ 0 \rangle$ P-centered Voronoi polyhedra beyond the first coordination environment are greater than that of $\langle 4\ 0\ 0\ 0 \rangle$ Voronoi polyhedra in the Li₂S–P₂S₅ glasses, as shown by black dotted lines in Fig. 3(a), which is consistent with the coordination number for P–Li correlation, N_{P-Li} . This increase in the fraction of higher-index Voronoi polyhedra occurs with increasing Li₂S content, which indicates that the number of Li⁺ ions around the PS_x polyhedral anion increases. On the other hand, the results for the Li-centered Voronoi polyhedral, shown in Fig. 3(a) as blue solid lines, have no dependence on the Li₂S content, which is also consistent with the coordination number for Li–P correlation, N_{Li-P} . Although the distribution of Li⁺ ions has not been characterized, it has been found that the simple Voronoi polyhedra for Li-centered polyhedra are dominant in the DFT/RMC model owing to the consideration of the electron state for Li⁺ ions in the DFT calculation. It is suggested that the free volume around PS_x polyhedral anions allows the distribution of Li⁺ ions at a higher Li₂S content.

The extent of polyhedral connection between PS_x and LiS_x polyhedra in the Li₂S–P₂S₅ glasses through corner, edge, and face sharing is calculated as shown in Fig. 3(b). The results are classified on the basis of PS_x polyhedral anions. The filled and hatched bars indicate corner sharing and edge sharing, respectively. The fraction of edge sharing increases relative to that of corner sharing with increasing Li₂S content, which is related to the bond angle distribution of the S–Li–S triplet. This means that an increase in the

Fig. 4 Relationship between the bond length and the coordination number for the Li-S (a) and S-Li (b) correlations derived using the DFT/RMC model.

Li₂S content does not affect the local coordination environment of Li⁺ ions, and the free volume around the PS_x polyhedral anion decreases. On the other hand, the fraction of each PS_x polyhedral anion in the 67Li₂S and 70Li₂S glasses is almost the same, although we expected a distinct difference between the compositions. This result shows the distribution of Li⁺ ions in each PS_x polyhedral anion.

To evaluate the free volume, we calculated the bond length relative to the coordination number of the S around Li, $N_{\text{Li-S}}$, and Li around S, $N_{\text{S-Li}}$, as shown in Fig. 4(a) and (b). The maximum bond length of 5.7 Å was determined from the Li-S-P bond length (3.2 Å + 2.5 Å), corresponding to the length calculated from polyhedral connection statistics. As can be seen in Fig. 4(b), $N_{\text{Li-S}}$ in this system has no composition dependence, which is consistent with the Li-centered Voronoi polyhedra. On the other hand, $N_{\text{S-Li}}$ in 75Li₂S was found to be larger than that of the other glasses as shown in Fig. 4(b), which suggests that the free volume around S ions is smallest in 75Li₂S. Intriguingly, $N_{\text{S-Li}}$ is larger for 70Li₂S than for 67Li₂S at 3.8 Å and over. Thus, as the Li₂S content increases in this system, the free volume around the Li ion does not change, while that around S decreases. The DFT/RMC structure is consistent with both the diffraction data and the Raman data (Fig. 5(a)), and we compared the electronic structure in terms of each PS_x polyhedral anion for the 70Li₂S glass. Fig. 5(b) and (c) show the partial density of states (*p*-DOS) of the 70Li₂S glass for the S 3*p*-orbital and P 3*p*-orbital, respectively. It is apparent that the orbitals form a hybrid orbital between the phosphorus and sulfur; the highest occupied molecular orbital (HOMO) is located at -4.0 to -0.5 eV and the lowest unoccupied molecular orbital (LUMO) is located at 1.5–5.0 eV. The positive charge of the P ion is large owing to the hybrid orbital. However, the *p*-DOS plots of the P ion reveal that the *p*-DOS for the P₂S₇ anion differs from those for the PS₄ and P₂S₆ anions (Fig. 5(c)). A shallow level appears near the bottom of the LUMO at approximately 2.0 eV in the P₂S₇ anion, which corresponds to a covalent bond between the P ion and the BS ion in the P₂S₇ anion. This electron transfer is expected to weaken the positive charge of the P ions, which attract Li⁺ ions to the P₂S₇ anions more strongly than the other PS_x polyhedral anions. Furthermore, the attracted Li⁺ ions tend to remain around the P₂S₇ anions, which may suppress the lithium ionic conduction in solid electrolytes. On the other hand, the P₂S₆ anion has almost the same electronic structure as the PS₄ anion and does not suppress the lithium ion conduction compared with the P₂S₇ anion, although we expected strong suppression of the Li ion conduction as shown by Hayashi *et al.* (2010a,b). It is well known that the diffusion of cations is accelerated by the polarization of anions (Alcaraz *et al.*, 2007; Trullàs *et al.*, 2003; Wilson and Madden, 1993). Also, the Li⁺ ion distribution is clearly affected by the polarization of anions (Tahara *et al.*, 2015), which means that the edge sharing between PS_x and LiS_y polyhedra is related to the lithium ionic conduction. Actually, the lithium ionic conductivity of 75 Li₂S without P₂S₇ anions is higher than that of the other glasses. Furthermore, Li₂S-SiS₂ glasses with added LiI exhibiting large polarization have a high ionic conductivity (Kennedy, 1986).

Structural Change of 75Li₂S·25P₂S₅ Glass During Annealing (Shiotani *et al.*, 2017)

The ionic conductivity of 75Li₂S·25P₂S₅ (75Li₂S) sulfide glass, which consists of glassy and crystalline phases, is improved by optimizing the conditions of the heat treatment, i.e., annealing. Fig. 6(a) shows the reduced PDF $G(r) = 4\pi r \rho_0 (g(r) - 1)$, where ρ_0 is the average atom number density and $g(r)$ is the pair distribution function obtained from the X-ray diffraction data, for each annealing treatment. On the basis of the previous section, the first peak at around 2.0 Å is related to the P-S correlation associated with the PS₄ tetrahedral anions and has no dependence on the annealing treatment. This means that the PS₄ tetrahedral anions remain in the structure during the crystallization. On the other hand, the relative intensities of the second and third peaks at around 3.3 and 4.1 Å, respectively, which are related to the S-S correlations as shown in Fig. 6(b), change between the glassy and crystalline phases. The second peak decreases upon crystallization, whereas the third peak increases. The peak at around 7.0 Å is related to the P-P correlation, as shown in Fig. 6(c), and increases upon crystallization, which indicates the formation of ordered PS₄ tetrahedral anions.

Even though the ionic conductivity increases during the optimized annealing, the differential PDF analysis indicates that the glassy structure undergoes no structural change in the sulfide glass-ceramic electrolyte at a crystallinity of 33.1% after annealing at

Fig. 5 (a) DFT/RMC model of 70Li₂S glass. Green, Li; purple, P and PS polyhedral anions; yellow, S. Polyhedral partial DOS for (b) S *p*-orbital and (c) P *p*-orbital of 70Li₂S glass.

200°C. We observed the formation of a nanocrystalline phase before the crystallization from the X-ray and electron diffraction patterns, which means that Bragg peaks were deformed. Thus, the ionic conductivity in the mixture of glassy and crystalline phases is improved by the coexistence of the nanocrystalline phase. Fig. 7 summarizes the crystallinity under each annealing condition. As can be seen, the ionic conductivity decreased after crystallization. It is well known that glasses have long-range density fluctuations in their structures (Wright, 2005; Fischer, 1993). Such fluctuations may be related to the improvement of ionic conductivity by the

Fig. 6 Reduced pair distribution functions, $G(r)$, obtained from a Fourier transformation of $S(Q)$ and atomic configurations for the $75\text{Li}_2\text{S} \cdot 25\text{P}_2\text{S}_5$ glasses: (a) $G(r)$ before annealing and after annealing at 120, 180, 200, 240, and 270°C. (b) Typical atomic configuration of S-S correlations. The correlations at around 3.3 and 4.1 Å are connected by pink and green lines, respectively. structural relaxation caused by the annealing treatment. However, the d-PDF indicated that the glassy structure shows no structural change in the sulfide glass-ceramic electrolytes. On the other hand, Schirmeisen *et al.* suggested that the fast ionic conduction of mobile ions in nanostructured LiAlSiO_4 glass ceramics is caused by the local movement of ions at the interfaces between the glassy phase and embedded crystallites. The existence of an electrical relaxation process with a very low activation energy, which is absent in pure LiAlSiO_4 glass, has been demonstrated by time-domain electrostatic force spectroscopy (Schirmeisen, 2007). Actually, we observed the formation of a nanocrystalline phase in the diffraction pattern after the annealing, which means that the Bragg peaks were deformed. Moreover, the nanocrystalline phase was verified by TEM and electron diffraction. Fig. 8(a) and (b) show bright-field (BF) images of sulfide glassy electrolytes before annealing and after annealing at 180°C, respectively. The electron diffraction

Fig. 8 TEM images and selected area electron diffraction patterns of the 75Li₂S·25P₂S₅ sulfide glass ceramic. (a,b) Bright-field images before annealing and after annealing at 180°C. (c,d) Selected area electron diffraction patterns obtained from the bright-field images.

patterns obtained from the BF images are shown in **Fig. 8(c)** and **(d)**. Spots can be seen in the electron diffraction after annealing that did not exist before annealing according to this preliminary analysis, as also reported by Tsukasaki *et al.* (2017). Thus, we suggest that the existence of such nanocrystalline phases, which are a minority component in the glass ceramic, will lead to greater ionic conduction than that of a pure sulfide glass.

Young's Moduli of the Sulfide Glasses (Kato *et al.*, 2018a,b)

Li₂S–P₂S₅ glasses have low Young's moduli (18–25 GPa) and excellent formability, allowing them to be highly densified by room-temperature pressure sintering (Sakuda *et al.*, 2013). These mechanical properties of the sulfide electrolytes contribute to the formation of a good contact at the solid-solid interfaces between the solid electrolytes and electrode active materials, leading to the excellent electrochemical performances of all-solid-state batteries. We summarize the Young's moduli of sulfide glasses using mean atomic volumes (Soga *et al.*, 1976) because the ion packing densities of the glasses can be easily estimated by calculating the mean atomic volumes from their densities. Young's moduli and the calculated mean atomic volumes of the Li₂S–P₂S₅ glasses are shown in **Fig. 9**. Young's modulus increases with decreasing mean atomic volume. The decrease in the mean atomic volume in the Li₂S–P₂S₅ glasses is associated with structural changes. The main anions in these glasses change from PS₃^{3–} (meta-thiophosphate) to P₂S₇^{4–} (pyro-thiophosphate) and PS₄^{3–} (ortho-thiophosphate) with increasing Li₂S content, suggesting that the anions change from a chain to an isolated structure by breaking the bridging structure of the P–S–P bonds as mentioned in the previous section (Ohara *et al.*, 2016). It is considered that mean atomic volume decreases (and ion packing density increases) with the increasing

Fig. 9 Young's moduli and mean atomic volumes of $\text{Li}_2\text{S-P}_2\text{S}_5$ glasses.

Fig. 10 Relationship between mean atomic volume and Young's modulus for $\text{Li}_2\text{S-P}_2\text{S}_5$ sulfide glasses (blue area) and other silicate (orange area), phosphate (green area), borate (gray area), and chalcogenide (purple area) glasses.

isolation of the anions in their glasses, which is a possible reason for the increase in Young's modulus. **Fig. 10** shows Young's moduli of sulfide glasses (Kato *et al.*, 2018a; Sakuda *et al.*, 2013), along with those of oxide glasses (Ashizuka and Sakai, 1983; Ashizuka *et al.*, 1983; Takahashi and Osaka, 1983) and other chalcogenide glasses (Guin *et al.*, 2002; Mel'nichenko *et al.*, 2002, 2009). In general, there is a good correlation between Young's modulus and mean atomic volume. As can be seen in this figure, oxide glasses have higher Young's moduli and smaller mean atomic volumes, while chalcogenide glasses have lower Young's moduli and larger mean atomic volumes. The sulfide glasses are in the intermediate region between the oxide glasses and other chalcogenide glasses. The Young's moduli of sulfide glasses are smaller than those of garnet-type $\text{Li}_7\text{La}_3\text{Zr}_2\text{O}_{12}$ and perovskite-type $\text{Li}_{0.33}\text{La}_{0.57}\text{TiO}_3$, known as oxide solid electrolytes (100–200 GPa) (Matsui *et al.*, 2014; Ohara *et al.*, 2010; Wolfenstine *et al.*, 2018). Note that one of the factors causing the deterioration of the all-solid-state batteries is the volume change caused by charging and discharging of the electrode active material. If a solid electrolyte at the interface with an electrode active material is too hard, the volume expansion of the electrode active material cannot be tolerated, and either the electrode active material or the solid electrolyte is destroyed at the interface. Furthermore, the interface between the electrode and the solid electrolyte may be lost when the electrode active material shrinks. To maintain adhesion at the interface between the electrode and the solid electrolyte during such a volume change in the electrode active material, the solid electrolyte needs to have a certain "softness". The Young's modulus of a sulfide electrolyte is smaller than that of an oxide electrolyte. The mechanical properties of the sulfide electrolytes contribute to the formation of good contacts at the solid-solid interfaces between the solid electrolytes and electrode active materials during charging and discharging. Kato *et al.* evaluated the discharge capacity of all-solid-state batteries using two electrolytes with similar ionic conductivities and different Young's moduli ($75\text{Li}_2\text{S} \cdot 25\text{P}_2\text{S}_5$ glass: $2.4 \times 10^{-4} \text{ S cm}^{-1}$, 23 GPa, and $70(\text{Li}_2\text{S-P}_2\text{S}_5) - 30\text{LiI}$ glass: $2.2 \times 10^{-4} \text{ S cm}^{-1}$, 17 GPa) (Kato *et al.*, 2018a,b). Si was used as an electrode material in this evaluation. It was found that $70(\text{Li}_2\text{S-P}_2\text{S}_5) - 30\text{LiI}$ glass with a small Young's modulus maintains a higher capacity after several cycles of charging and discharging (**Fig. 11**). Thus, the Young's

Fig. 11 Cycle performance of all-solid-state cells using Si composite electrodes containing 75Li₂S–25P₂S₅ (75–25) and 70(Li₂S–P₂S₅)–30LiI (50–50–30LiI) glass electrolytes.

modulus of the solid electrolyte is one of important factors to be considered when constructing an all-solid-state battery with high performance.

Concluding Remarks

This chapter introduced the development of sulfide solid electrolytes with a high lithium ion conductivity and the structural features of typical sulfide glasses. In addition, the mechanical properties of sulfide solid electrolytes were described. Through recent research and development, many solid electrolytes having an ionic conductivity of 10^{-3} S cm⁻¹ or more have been found, and some solid electrolytes with ionic conductivity on the order of 10^{-2} S cm⁻¹ have also been discovered. On the other hand, to obtain satisfactory performance with these solid electrolytes, it is important to construct a suitable interface between the electrode active material and the solid electrolyte in an all-solid-state battery and to maintain the interface during long-term charge-discharge cycles. Attention must also be paid to the mechanical properties, which are closely related to the interface phenomena, and thus the Young's moduli of sulfide solid electrolytes are focused on. From the knowledge obtained so far, the further development of solid electrolytes is expected, and we hope the commercial realization of all-solid-state batteries that will enrich to our daily lives.

Solid Oxide Fuel Cells

Alessandra Sanson and Angela Gondolini, National Research Council, Institute of Science and Technology for Ceramics, Faenza, Italy

Introduction

The first description of the so-called 'gaseous voltaic battery' or 'wet cell battery' belongs to Sir William Grove: "I will...mention one [experiment] which goes a step further than any hitherto recorded; and affords, I think, an important illustration of the combination of gases by platinum (Grove, 1839, 1842). Simultaneously, Shönbein suggested the explanation of this polarization phenomenon as a consequence of a series of galvanic experiments concluding "...that the current in question is caused by the combination of hydrogen with oxygen... and not by contact" (Schonbein, 1839) (referring to a controversially discussed 'contact theory' widely used in the early nineteenth century for the explanation of electrical phenomena). In comparison to batteries with liquid electrolytes, which were also developed during this period (Daniell element), the main disadvantage of the fuel cell was considered the need of continuous gas supply. Batteries became therefore the more convenient, practical, and compact choice of small-scale power supply until today.

It was necessary to wait almost one century for Baur and Preis to construct the first solid oxide fuel cells (SOFCs), i.e., galvanic cells using a solid oxygen ion conductor as electrolyte (Baur and Preis, 1937). In this attempt they investigated various porcelains, clays, and zirconia-based materials as solid electrolytes. A tubular stack test consisting of eight zirconia tubes filled with coke (as fuel and anode) and a kind of powder bath of magnetite used as cathode was finally able to deliver a power of 0.045 W (i.e., 0.18 W l⁻¹ or about 120 μA cm⁻²).

Apart from zirconia, the materials selection of these first SOFCs refers to a "fuel element" (Baur and Treadwell, 1916), which is known today as molten carbonate fuel cell. Regarding the applicability of their fuel cells, Baur and Preis concluded that their modified zirconia materials would fulfill all technical requirements but were hindered by their high price.

SOFCs are nowadays one of the most promising devices for stationary clean energy production, due to their minimal Green House Gas (GHG) emissions, fuel flexibility (from hydrogen to hydrocarbons and biogas), high efficiency and power density.

SOFCs Working Principle

The SOFC core is constituted by a dense solid electrolyte sandwiched between two porous electrodes (anode and cathode) as presented in Fig. 1. SOFCs can be divided in anionic and protonic on the basis of the ion that migrates through the electrolyte membrane. In anionic-SOFC the electrolyte is an oxygen ion transport material, while in protonic-SOFC is a proton conductor. As reported in Fig. 1, the different ion involved in electrolyte conduction governs the side at which the water is collected even if the oxidation and reduction sides remains the same; the reduction of oxygen to produce O²⁻ takes place at the cathode while the H₂ oxidation to form H⁺ species at the anode. The electrons produced by the reactions finally flow through the external circuit that connect the electrodes and allows the collection of the current.

While, in recent years protonic SOFCs technology has reached significant advancement in terms of performance and reliability (Singh et al., 2019), up to now, only anionic SOFC have found commercial applications.

Independent in shape and size, state-of-the-art SOFCs typically contain 8 mol% yttria-stabilized zirconia (8YSZ, Y_{0.15}Zr_{0.85}O_{1.93}) as electrolyte, a perovskite-based cathode (strontium-substituted modifications of lanthanum manganite like La_{1-x-y}Sr_xMnO₃ with 0.15 < x < 0.4 and 0 < y < 0.05) and a composite of 8YSZ and metallic nickel as anode.

Description of the Various Types of SOFCs

Solid oxide fuel cells can be mainly grouped into tubular and planar designs. Both types can consist of one or several single cells per stacking unit, i.e., on a single tube or in a single multilayer. Depending on the application, tubular SOFCs have dimensions from needle-like to lengths of about 1.5–2 m for rapid start-up times and large gross power, respectively. On the other hand, the planar is the most common SOFC design thanks to its higher performance. This architecture can lead to two different stacks containing metallic or ceramic interconnect material as well as with cells with thick (electrolyte-supported, 1st generation cells) or thin (electrode-supported, 2nd generation cells) membranes with thicknesses usually of 150–250 μm and 5–20 μm, respectively (Tietz, 2003; Blum et al., 2005). The size of technologically relevant planar cells varies from 10 × 10 cm² to 25 × 25 cm² or corresponding areas in round or rectangular shape.

The today general tendency of reducing the operating temperature from about 1000°C to 500–800°C favors cell designs with thin electrolytes, lower ohmic resistance and, therefore, higher power density, passing from the 1st to the 2nd generation of cells (as schematized in Fig. 2). For this reason, many developers have considered electrode-supported cells the best choice for realizing SOFCs operating at reduced temperature (Tietz, 2003; Blum et al., 2005).

Fig. 1 Schematic representation of the anionic (on the left) and protonic (on the right) SOFC working principle.

Fig. 2 Schematic illustration of the SOFC generations architectures.

The term 'electrode-supported' has been initially introduced to explicitly indicate that in such fuel cells the mechanical stability is transferred from the thick, dense electrolyte layer to an even thicker, porous electrode (0.5–1.5 μm). The second generation of cells could be supported on the anode or cathode side. Although the cathode-supported configuration showed better structural stability and lower-cost cathode material (Gondolini *et al.*, 2012; Su *et al.*, 2015) the anode-supported one is preferred for the easier manufacturing. During recent years, more interest is devoted to the 3rd generation SOFCs (Fig. 2) in which the mechanical strength is given by the electrode side, though not necessarily by the electrode substrate. In all these cases, the substrate is always porous to allow gas transport to and from the anode. The materials used for such substrates are metals or alloys, or even refractory ceramics. In the case of insulating substrates, they only deliver the fuel gas to the anode and the current path has to be established along the substrate surface instead of passing perpendicular to the substrate surface as in electrically conductive substrates. In the case of metallic substrates the thermomechanical compatibility is one of the main issue to be faced, because they often have higher thermal expansion coefficients than the other cell components. Ferritic stainless steel is one of the most considered materials thanks to a coefficient of expansion similar to the ones of the cell ceramic materials (YSZ, GDC, electrolyte, or anode functional layer). Furthermore, its lower cost in comparison to either YSZ or GDC, cathodic and anodic materials leads to an overall reduction of the cost of the device. However, metal-supported cells (MS-SOFC) suffer of strong cation interdiffusion between the different components during manufacturing and severe corrosion at high operating temperature ($\geq 800^\circ\text{C}$). For this architecture, colloidal and wet-colloidal methods are then used to produce and sinter thin films of electrolyte on the anode substrate and therefore lower the cell manufacturing and reach operating temperatures compatible with stainless steel (Krishnan, 2017; Tucker, 2010). On the porous substrate, the cell components are deposited in the sequence anode–electrolyte–cathode. Normally the coatings are realized by screen printing, slurry coating, wet powder spraying, or atmospheric plasma spraying. Even if the substrate is made of the anode material, Ni/8YSZ, it has been found beneficial for the electrochemical performance to apply an additional anode layer called "functional anode" having a finer microstructure and therefore a better electrocatalytic conversion capability of the fuel gas. The layers typically have thicknesses of 5–20 μm for the functional anode, 10–20 μm for the electrolyte, and 50–80 μm for the cathode (Fig. 3). Also, the cathode is nowadays composed of two layers: an electrochemically fine-grained composite of the electrolyte material and the electrocatalyst (lanthanum manganite) and a coarse current collection layer supplying air and electrons to the composite layer.

Fig. 3 Microstructure of an anode-supported SOFC with a 10 μm thick solid electrolyte. In this magnification, the anode would end up in a thickness of about 100 μm (?). Courtesy of Forschungszentrum Jülich.

The Technological Trends During the Recent Years

Three main areas of research are addressed for making SOFC technology competitive with other electricity generators: (1) Reduce the costs of materials, components, cells, and stacks, e.g., by applying low-cost technical-grade raw materials, by reducing the manufacturing costs (e.g., reduction of sintering temperatures, reduction of sintering steps, application of conventional ceramic, or metallurgical processing methods, simplification of production processes, including the use of additive manufacturing techniques), by decreasing the thickness of components, especially the anode substrate, by the integration of cheaper metal supports and interconnect materials. (2) Decrease the operating temperature to obtain higher performance, power density, and efficiency. Simultaneously, this implies lower degradation processes and costs (due to a smaller number of cells required for a certain gross power). The higher performance gives more flexibility in operation and that is why the switch from electrolyte-to anode-supported designs has taken place. Performance has been further increased by using new cathode materials, lowering the electrolyte thickness and optimizing their microstructures. (3) Decrease the degradation processes and increase durability and reliability (in operation and in component fabrication). Different studies have revealed that these goals are more easily achieved in small-scale applications (1–5 kW) than with larger systems (100–1000 kW). Several degradation phenomena have been addressed like chromium poisoning of the cathode, contact resistances at the interfaces (especially at the interconnect) the long-term stability of electrolytes, anodes, and cathodes, and the influence of fuel gases and contaminants (coking, sulfur poisoning). The development of alternatives anodes with respect to NiO-based material and cathodes with respect to the Cr and Co-based ones moves the SOFC development in this direction addressing several issues of cell degradation such as Ni coalescence and agglomeration, carbon and sulfur tolerance, robustness during the redox cycling and cation interdiffusion. In the same direction, the development of different

Table 1 Ionic conductivity (σ_i) of different oxygen ion conductors (in S cm^{-1})

Material	σ_i at 800°C	σ_i at 600°C

buffering and protective layers able to prevent cation diffusion between the different elements of the cell. Metal support technology would increase mechanical ruggedness, redox tolerance and rapid thermal cyclability while recently additive manufacturing techniques have opened new ways to customize and potentially reduce the cost, of the single cell.

Progress in Materials Development and Processing

Electrolytes

As mentioned before, SOFCs use a solid oxide ion conductor as electrolyte material. This material must have sufficient ionic conductivity for O^{2-} or H^+ ions at operating temperature. To lower the operating temperatures, thin electrolyte films on porous electrode substrates are now preferred. The four main material systems for oxygen conductive electrolyte are partially cation substituted ZrO_2 , CeO_2 , and LaGaO_3 as well as apatites. The ionic conductivities of these solid electrolytes are listed in **Table 1**.

Apart from the apatite $\text{La}_{10}\text{Si}_6\text{O}_{27}$, the other solid electrolytes have ionic conductivity about 2 times higher than that of 8YSZ at 800°C and lower temperatures. Therefore, the improvement can be significant for electrolyte-supported cells but is negligible for electrode-supported cells. Assuming an electrolyte thickness of 10 μm and ionic conductivity of 0.05 S cm^{-1} and 0.12 S cm^{-1} for 8YSZ and ScSZ, respectively, at 800°C (**Table 1**), this leads to an ohmic loss over the electrolyte layer of about 20 m Ω and 8 m Ω , respectively. These values are much smaller than the overpotentials at the cathode which are in the range of 100–400 m Ω . Only the apatite, an ion conductor with excess oxygen ions on interstitial sites instead of oxygen vacancies (as in the other materials), has a different temperature dependence and smaller activation energy of the ionic conductivity. Therefore, the value at 800°C is rather low, but the material surpasses the conductivity of 8YSZ at 600°C and outperforms also the other materials at and below 500°C (**Nakayama and Sakamoto, 1998**). During exposure at 1000°C it was found in several studies that 8YSZ samples showed a higher decrease of conductivity than samples with a higher Y_2O_3 content. The best conductivity values after annealing were reached by samples with 10 mol% Y_2O_3 . The aging of zirconia stabilized with 7.8 mol% Sc_2O_3 directly correlated with the decrease in conductivity and temperature. Similar investigations with Sc_2O_3 contents between 8 mol% and 12 mol% showed only slight degradation effects after aging at 1000°C (up to 6000 h). Samples with 11 mol% Sc_2O_3 remained nearly unchanged with respect to conductivity. Up to the present, however, the lower price and larger availability of yttria lead to its dominant use as a stabilizer in contrast to scandia.

Below 800°C the conductivity of CeO_2 -based compounds is several times higher than the traditional 8YSZ electrolyte. For this reason, this material is one of the best candidates for the production of SOFC working at intermediate temperature (600–800°C). However, Ce^{4+} in the CeO_2 structure is partially reduced to Ce^{3+} at high temperature or in reducing atmosphere with a consequent lowering of the ionic conductivity, increasing of electronic conductivity and lattice expansion that lead to the decrease of the open circuit voltage and of the mechanical properties of the complete cell. To improve the reliability of this material two main approaches are generally used. The first one is improving the material stability in reducing environment by co-doping rare earth elements, a practice that leads to an increase of ionic conductivity. Y, Gd, and Sm show the lowest size mismatch, exhibiting the highest conductivity as summarized in **Table 2**.

On the other hand, an electronic barrier layer (such as 8YSZ film) can be added between GDC and anode to improve the stability of the entire cell (Wang *et al.*, 2019). However high process temperatures lead to a GDC and YSZ interaction/interdiffusion during the sintering process at 1200°C reducing the cell performance; in this case low temperature heating treatments and processes are preferentially used for SOFC development. Cerium oxides-based compounds are generally applied for the development of the technology at intermediate temperature, (between 600 and 800°C) and for low temperature SOFC (350–600°C) mixed with alkali carbonates (Na, Li, K, and mixtures of them). Among several formulations, sodium carbonate-SDC composites (Na_2CO_3 -SDC) is one of the most promising composite due to its superior conductivity and to the high melting point of Na_2CO_3 , which prevents the liquid phase formation in the operative range (below 600°C) (Khan *et al.*, 2018).

Pure lanthanum gallate is a poor ionic conductor. When replacing La^{3+} or Ga^{3+} ions by Sr^{2+} or Mg^{2+} ions, high ionic conduction is obtained (Ishihara *et al.*, 1994). Time-dependent measurements on $\text{La}_{0.8}\text{Sr}_{0.2}\text{Ga}_{0.85}\text{Mg}_{0.15}\text{O}_{2.825}$ (Huang *et al.*, 1998) have shown that the conductivity at 700°C in air is nearly unchanged, amounting to 0.073 S cm^{-1} over a period of 200 h. LSGM presents very good chemical stability in oxidizing and reducing atmosphere and shows ionic conductivity in a wide range of oxygen partial pressures. However, it reacts with NiO of the anode to form lanthanum–nickel oxide. This leads to a deterioration of the ionic conduction and the anode function. This reaction can be suppressed applying a diffusion barrier layer of $(\text{Ce,Sm})\text{O}_{2-x}$. On the other hand, the preparation of thin film LSGM dense electrolyte is more difficult in respect to CeO_2 -based and YSZ materials; for this reason the development of mature thin film deposition technology is now considered to push the development of LSGM electrolytes (Wang *et al.*, 2019).

In terms of protonic conductors, the most considered materials are the solid solutions obtained coupling two barium-based perovskites: BaCeO_3 and BaZrO_3 (Hossain *et al.*, 2018). The former is more conductive but is severely unstable in CO_2 atmosphere, while the latter is stable but is definitely more refractive and less conductive. The solid solution between the two, eventually doped with Y^{3+} , gives rise to a reasonably stable material with good conductive properties.

Anode Substrates and Anodes

The most commonly applied anode material is a nickel/YSZ cermet produced starting from a mixture of nickel oxide and YSZ powder. In the final structure of the electrode, the nickel oxide is then commonly reduced to nickel during the start-up phase of the cell or stack by the prevailing fuel atmosphere. The nickel serves as a catalyst for the oxidation reaction of the hydrogen and is finely dispersed around the YSZ particles. The function of the zirconia skeleton is to stabilize the porous electrode structure, to create an extended reaction zone by increasing the number of three-phase boundaries, and also to adapt the thermal expansion coefficient between the nickel and the other cell components.

The demands for an anode substrate with good electrical conductivity, good gas permeability, and fine-grained homogeneous microstructure can be obtained by the powders currently used and were studied in detail for Ni/8YSZ anode substrates. Since the anode substrate accounts for more than 90% of the material expenditure of the ceramic parts, this component is the most promising candidate for saving material. Therefore, low-cost nickel oxides of technical powder quality were considered (Tietz *et al.*, 2000) to replace the NiO used hitherto which satisfies very high demands on quality.

The introduction of an additional anode functional layer (see Fig. 1), allowed to divide the two tasks of the Ni/8YSZ anode substrate, i.e., the mechanical stability and the electrocatalytic conversion of the fuel. In this way it was possible to separately improve the material properties of the anode functional layer and the anode substrate. Therefore new cermets based on Ni/ Al_2O_3 or Ni/ TiO_2 were synthesized (Meschke *et al.*, 2001) to match the thermal expansion coefficient of the 8YSZ avoiding the thermoelastic bending during cell fabrication (Steinbrech *et al.*, 1997) and to reduce the costs of the substrate. However, during cell fabrication, a severe interaction with the anode layer was observed due to liquid-phase sintering, which led to a detrimental decrease of electrochemical performance. The cermet obtained mixing Ni with the electrolyte powder is therefore still the most common material used as anode in SOFC.

Apart from cermets, other materials have been considered as anode substrate, i.e., able to support the mechanical strength of the cell, among them metals (ferritic steels) or ceramics with n-type conductivity are the most studied. These alternatives offer solutions for the highly demanded reoxidation stability of the anode cermets, because they do not undergo a strong volume expansion during reoxidation. In particular, metal supported SOFCs (MS-SOFCs) have attracted considerable research interest for cost reduction, improved mechanical robustness and thermal shock resistance which make this technology attractive also for mobile applications. Many materials have been investigated for use as metal supports for SOFC and are typically either nickel or iron based. The coefficient of thermal expansion (CTE) of the metals has to be matched to that of the electrolyte to enable rapid thermal cycling and to increase cell durability. Table 3 lists some candidate materials to be used as metal support with their respective CTE.

Ni have been used by several research groups as support material. However, its low redox cycling tolerance, high susceptibility to coking and sulfur species, high cost and poor CTE matching with the electrolyte, restricted its application. The addition of Fe to Ni (in particular with weight ratio close to 1:1) allows to lower cost, improves the CTE but does not bring to any improvement in terms of stability in oxidant environment (Krishnan, 2017). Ni–Al porous substrates were also used for the production of MS-SOFC. Even the CTE with the electrolyte are different the degradation in the layers interface has not been observed over 100 h of operation in dry hydrogen (Solovyev *et al.*, 2015). On the other hand, ferritic stainless steels, have received significant interest due to their low cost, thermal compatibility with YSZ and CGO and better stability than Ni-based supports. Moreover, these alloys

Table 3 Candidate metal supports for MS-SOFC with CTE. The CTE of electrolytes (YSZ, CGO-LSGM) are in the order of 10–12 ppm K⁻¹

Metal	CTE (ppm K ⁻¹)
NiCrAlY, NiCrAl	15–16
Ni–Al	15
Ni	16.5
Ni–Fe (1:1)	13.7
300-Series stainless steel	18–20
400-Series stainless steel	10–12

produce a thin, continuous, conductive chromia scale that is beneficial for the longevity of the cell. However, to improve the durability of these systems and avoid severe corrosion, ferritic steels have to be coated increasing the complexity of the overall cell manufacturing. In addition ferritic steel-supported SOFCs have to be produced using protection atmosphere during thermal cycles to hinder severe corrosion in air and Fe and Cr diffusion in the electrodic layer, that may lead to losing the n-type electronic conductivity of highly conductive ceramics (Marina *et al.*, 2002). To avoid that, NiCrAlY and NiCrAl supports have been considered for the production of MS-SOFC. The presence of Al in the foam produces, in fact a continuous Al₂O₃ scale at the surface of the metal that improve its oxidation resistance and make possible to thermally treat the layers at low temperature (up to 1050°C) in oxidant environment (Gondolini *et al.*, 2017). The cell produced showed decent stability after 54 redox cycles even if a partial delamination of anode substrate-anode functional layer occurs due to the volume variation between nickel and nickel oxide (Costa *et al.*, 2018).

Besides mechanical damage during reoxidation, anode cermets suffer also from sulfur poisoning or coking from the fuel gas, if the methane contains contaminants or insufficient amounts of water for internal reforming, respectively. Although efficient and compact desulfurizers are available and a controlled system operation can solve these problems, there is a continuous search for ceramic anode materials overcoming these drawbacks. In most cases, perovskite materials have been investigated for this purpose (Atkinson *et al.*, 2004) such as (Sr,La)TiO₃, (Sr,Y)TiO₃, (La,Sr)(Cr,Mn)O₃, (La,Sr)CrO₃, (La,Sr)MnO₃, (La,Sr)FeO₃, (Sr,Mg)MoO₆, (Sr,Fe)MoO₆, etc.

SrTiO₃-based compounds have attracted attention due to their good conductivity, dimensional stability and higher tolerance and resistance towards sulfur poisoning and carbon depositions. Tuning the substitution and stoichiometry levels on A- and B-sites of SrTiO₃-based perovskite (La, Nb, Y, and Ce) allows to achieve good catalytic activity for hydrogen oxidation, electrical conductivity and chemical stability in respect to the other perovskite-based materials at 700–850°C. The electrical conductivity of Y-SrTiO₃(YST) materials changes with the concentration of strontium in their structure, however the addition of small amount of Ni or ceria impregnation is necessary to improve its hydrogen catalytic activity (Shu *et al.*, 2019). Lanthanum-doped SrTiO₃ (LST) has shown good electronic conductivity and chemical/thermal stability in wide ranges of temperature, oxygen partial pressure and in presence of H₂S. However, this material shows lower electrochemical performance than Ni-based anode under humidified hydrogen. For this reason, LST is combined with other oxide ion conductors (CeO₂-based compounds and YSZ) and doped with different elements that precipitates in form of nanoparticles (Ni, Co, Fe, Pd, Ru, etc.) under strong reducing condition to improve its electrochemical and catalytic performances (Shu *et al.*, 2019; Gondolini *et al.*, 2018).

LaSrCrO₃-based materials (LSCr) are applied as SOFC anode materials especially when doped with cations with lower coordination number (Mn, Co, Fe, etc.) that enhanced LSC catalytic activity. LSCr doped with manganese is one of the most used perovskite thanks to its high temperature stability, good resistance to carbon deposit and redox stability (Tao and Irvine, 2003). Doping with Iron (LSCrF) on the other hand, gives a composition with excellent activity in the oxidation of H₂S and CH₄, however it exhibits poor electrical conductivity in respect to La-SrTiO₃-based compositions (Shu *et al.*, 2019). Also, nichelates (such as La_{0.75}Sr_{0.25}Cr_{0.5}Mn_{0.44}Ni_{0.66}O_{3–d}) and molibdates (such as Gd₂Ti_{1.4}Mo_{0.7}O_{7–d}, Sr₂MgMoO_{6–d}) have recently showed very promising properties as anodes (Sreedhar, 2019).

As pure ceramics, however, the cell performance has always been lower than for the conventional Ni/8YSZ anode, because these anodes either do not have sufficient electronic or ionic conductivity or are not catalytically active. To improve the performance small additions of catalysts, element doping and the incorporation of ceramic composites is often considered. Further research and development are anyway necessary to achieve properties comparable with the ones shown by conventional anodes.

Cathode

Perovskite materials of the ABO₃ type are generally used as the cathode material mixed with an electrolytic phase to increase the triple phase boundary (TPB) and therefore the cell efficiency. A frequently used cathode material is lanthanum manganite (LaMnO₃, LSM) with substitutions of strontium or calcium at the A-site (Minh, 1993). Both A- and B-site substitutions have been

investigated extensively, so that these ceramics can be selected according to the demands made on their properties such as thermal expansion coefficient, electronic or ionic conductivity, and chemical interaction with the electrolyte. LSM is still the most popular cathode material in SOFC application, due to the thermomechanical compatibility with YSZ. LSM however, chemically interacts with YSZ at temperature higher than 1300°C, for this motivation a CeO₂-based coating is generally deposited between the electrolyte and cathode materials. The composite between LSM and YSZ is, up to now, the best combination of stability, performance and simply manufacturing (Sreedhar *et al.*, 2019). Lanthanum or strontium cobaltites have attracted much attention because of their high mixed ionic–electronic conduction. Indeed, (La,Sr)CoO₃ shows a higher cathodic performance than (La,Sr)MnO₃, but the cobaltite possesses a very different thermal expansion in comparison to YSZ (Tietz, 1999) and it reacts easily with this electrolyte at high temperatures ($\geq 1000^\circ\text{C}$), forming highly resistive La₂Zr₂O₇ or SrZrO₃ compounds. These unfavorable solid-state reactions can be avoided, when a ceria-based diffusion barrier layer is applied (Chen *et al.*, 1995). As a compromise between thermal expansion mismatch and electrochemical performance, the composition La_{0.6}Sr_{0.4}Fe_{0.8}Co_{0.2}O₃ (LSFC) has been established as an alternative to (La,Sr)MnO₃ cathodes for reduced operating temperatures since the mid-1990s (Chen *et al.*, 1995; Sahibzada *et al.*, 1997). The advantage of such mixed ionic–electronic conducting cathodes relies on their increased reactive catalytic surface area over the whole perovskite grains. Therefore, the charge transfer of adsorbed oxygen atoms takes place directly on the perovskite surface. The increase in oxygen ion conductivity and hence in mixed conductivity is generally correlated with an increasing thermal expansion (Ullmann *et al.*, 2000). Therefore, an improvement of the transport properties is always linked to an increasing mismatch in thermal expansion related to the other cell components. In recent years, many studies have been devoted to the improvement of the electrochemical activity and microstructure stability of LSCF-based electrode materials to develop highly active and durable oxygen electrodes for intermediate and low temperature SOFCs. For doing so, different strategies including, nano-architecture, surface decoration, interface manipulation or design were considered. This led to the increase of electrocatalytic activities, reduction of the activation energy-area specific resistance, reduction in the surface segregation and chemical reactivity promoting microstructural stability and resistance towards contaminants such as chromium, sulfur, and boron under SOFC operation conditions (Jiang, 2019).

A rough classification of cathode materials regarding their electrocatalytic activity follows the order: LaCoO₃ > LaMnO₃ > LaFeO₃ > LaCrO₃. The electrocatalytic activity also varies with alkaline-earth concentration in the perovskite. Generally, cobalt-based compositions present higher conductivity with respect to the cobalt-free ones; on the other hand, CTE mismatch between cathode and electrolyte is disadvantageous for long time operation. For this reason, additional studies on cobalt-free perovskite materials are necessary to design higher performance cathode compositions (Hashim *et al.*, 2019).

Interconnect

The interconnect in SOFC stacks is the component that electrically connects the single cells and in planar systems additionally separates the gas compartments from each other and it is therefore subjected at the same time to highly reducing and oxidizing atmospheres. Interconnects must satisfy many different criteria: good electrical conductivity, gas tightness (to prevent O₂ and H₂ mixing), chemical compatibility with the adjacent components of the fuel cell, high corrosion resistance to the reaction gases, matched thermal expansion ($10\text{--}13 \times 10^{-6}\text{K}^{-1}$) and last, but not least, reasonable costs. In order to meet these requirements, two classes of materials have been developed for interconnects, namely ceramic and metallic materials (Anderson and Tietz, 2003). Whereas ceramic interconnects played a dominant role in the early SOFC developments, metallic interconnects are nowadays the most used materials due to the general trend toward lower operating temperatures (Bianco *et al.*, 2019).

Practically all ceramic interconnects which have been developed are based on LaCrO₃ for its strong chemical stability and excellent electric conductivity at temperature around 1000°C in fuel gas atmosphere. However, at lower temperatures lanthanum chromites exhibit oxygen deficiency as a consequence of their p-type semi conductive behavior with consequent reduction of electrical conductivity. In addition, lanthanum chromites show undesirable swelling in reducing atmospheres caused by the reduction of Cr⁴⁺ ions to Cr³⁺ and the formation of oxygen vacancies leading to strong internal stresses and possible cracking during operation.

Apart from these physical handicaps, the materials costs as well as the fabrication and processing costs due to the low sinterability are the most critical issues for ceramic interconnects.

Hence, while the advantages of metallic interconnects are obvious (high electrical conductivity, good ability for processing, and lower cost) they are strongly affected by corrosion and increasing resistance during operation, chromium evaporation, low high-temperature strength.

The long-term stability of the metallic interconnect is essentially governed by its corrosion characteristics. The materials used for interconnects are alloys forming chromium or alumina oxide (Bianco *et al.*, 2019). The former is preferred because it ensures sufficiently high conductivity of the thin oxide scales. Meanwhile several ferritic steels have been developed especially for SOFC application containing only very small amounts of aluminum and silicon to avoid the formation of highly resistive oxide scales and low amounts of manganese for the formation of (Cr,Mn)₃O₄ spinels as the outer corrosion scale (Quadackers *et al.*, 2003; Mehran *et al.*, 2019). Fe–Cr Alloy are at the moment the most considered materials for interconnects. In order to have suitable thermomechanical properties, however, the alloy is commonly modified with the dispersion of oxide particles of reactive elements such as Nb, Y, La, Ce, and Zr (Seo *et al.*, 2008). These oxides contribute to improve the scale adhesion to the substrate considerably reducing their growth and the outward Cr transport (Pint and Wright, 2005).

The main focus in interconnect development is still the improvement of the corrosion behavior, but also the reduction of contact resistance of the corrosion scales or in combination with coatings and the reduction of chromium evaporation to avoid a detrimental poisoning of the cathode with chromium species (Hilpert *et al.*, 1996). All these phenomena contribute mainly to the observed degradation of stack voltage during operation, but it is not yet clarified to what extent (Fontana *et al.*, 2012; Mehran *et al.*, 2019).

Protective and Contact Coatings

Many attempts have been made to reduce the damaging effect of chromium vapors on the cathode side by suitable protective layers. Other than being dense to prevent outward diffusion of chromium and inward diffusion of oxygen ions, the protective coating materials should possess high electrical conductivity ($ASR < 0.1 \Omega \text{ cm}^2$) and TEC not more than 10% different from the one of the interconnector, to ensure durability (Mah *et al.*, 2017).

Mainly two classes of compounds have been examined for this purpose: Perovskites and Spinel Oxide. Their function as diffusion barriers against volatile Cr species strongly depends on the quality of the layers (gas tightness, crack density).

As already mentioned, perovskites exhibit p-type electronic conduction and are stable in low oxygen partial pressure. The first perovskite to be developed was plasma-sprayed coatings of lanthanum chromite. These coatings are characterized by high contact resistances and high fabrication costs in comparison to ceramic methods using slurries or pastes. However, the reactivity of lanthanum chromite with metals, either with Cr- or Fe-based alloys, is low and the metal/ceramic interface is very stable under operating conditions. More recently ferrite-based composition such as LSCF have been considered as protective layer, but LSC still represent the most suitable material with ASR of $0.0028 \Omega \text{ cm}^2$ after 1600 h of operation at intermediate temperature (Tan *et al.*, 2019).

Spinel oxide of general formula AB_2O_4 are the most successful materials able to suppress chromium evaporation. The cubic spinel structure comprises divalent, trivalent or quadrivalent A and B ions in octahedral and tetrahedral sites respectively. The ratio between A and B cation governs the electrical conductivity and TEC of these materials. The highest conductivity up to now has been shown by $Cu_{1.3}Mn_{1.7}O_4$ even if the most studied compounds considered the Mn–Co System.

Chemical interactions between coatings and interconnect material increase when the alkaline earth content in the ceramic is increased. Often perovskite materials have been brought in contact with Cr-based alloys or steels and the formation of chromates (e.g., $CaCrO_4$ or $SrCrO_4$) was observed (Larring and Norby, 2000), leading to progressive decomposition of the perovskite material and a brittle interface. To reduce this effect, the application of cobalt oxide or cobalt manganese spinel between perovskite and alloy (Larring and Norby, 2000; Zahid *et al.*, 2004) as well as metals such as Nickel (Demeneva *et al.*, 2019) as being considered, showing a stable contact resistance with time.

Coating the ferritic steel Crofer22APU by wet powder spraying with a porous Co_3O_4 layer or a metallic Co layer leads to the formation of a new dense Cr-free reactive layer under the SOFC operating conditions (Zahid *et al.*, 2004). As a reaction product of Mn from the oxide scale of the steel and the Co_3O_4 layer, this dense layer may act as a barrier against vapor-phase transport of volatile Cr species. Contact materials are electrically conductive ceramics to improve the contact between interconnect and electrode. Whereas for the anode side metallic nickel is used (as mesh, foam, or paste), on the cathode side often ceramic cathode-like compositions are used, which possess conductivities in the range of $50\text{--}500 \text{ S cm}^{-1}$. Because there are no electrochemical requirements to be obeyed for the contact materials, they can vary significantly from the electrode materials and be optimized with regard to other physical and chemical properties than the electrodes. Apart from the electrical conductivity, the most important properties are the thermal expansion and the sintering behavior at assembling temperatures in the range of $800\text{--}1100^\circ\text{C}$. Because the contact layer thickness may vary between $30 \mu\text{m}$ and $200 \mu\text{m}$ and ceramic materials heat-treated below 1000°C are usually very porous, the specific conductivity of the material should be high. This is in fact the case for lanthanum cobaltites having specific conductivities up to 1700 S cm^{-1} . On the contrary, the thermal expansion of these cobaltites has a strong mismatch with the other cell components. For electrically conductive ceramics, therefore, a compromise between acceptable conductivity and tolerable mismatch in thermal expansion has to be made as for the cathode materials.

Regarding the deposition techniques, the choice depends on the materials to be deposited and the morphology of the surface considered. The most common are magnetron sputtering, screen printing, sol–gel dip coating and electrodeposition (Mah *et al.*, 2017).

Sealings

In planar SOFCs, gastight seals must be realized along the edges of each cell, along the outer edges of the stacking layers, and the gas manifold to separate the two gas compartments and to insulate the stacking layers from each other. There are different approaches that have been developed for sealing SOFCs: brazing, compressive seals, glass, glass ceramics, and glass composites (Smeacetto *et al.*, 2013). Irrespective to the material, the sealant must satisfy several different requirements: zero (or at least very low) gas permeability; good adhesion to the elements of the cell and interconnect; chemical, thermal and mechanical stability during manufacturing and operation; CTE compatible with the other elements; High electrical resistivity ($> 10^5 \Omega \text{ cm}$); minimum volatilization, elements diffusion, and reactivity with the operation gases; characteristics temperatures (softening, maximum shrinkage, etc.) compatible with the operation ones; superior thermal shock resistance; good sinterability, easy processing, and absence of defects; self-healing ability and obviously low cost (Tulyaganov *et al.*, 2013). Glass or glass ceramics are well known for joining of metals, especially the joining of steels (Donald, 1993) and are considered in great details as they can meet, in principle,

most of the requirements of an ideal sealant. Glass-ceramics in particular, are considered the most suitable candidates as their composition flexibility can be used to match the requirements of different materials. Many of these products are commercially available, but most of the sealing products are produced for low-temperature joining and room-temperature applications. However, no commercial product fulfills the requirement of a thermal expansion coefficient in the range of $10\text{--}13 \times 10^{-6}\text{K}^{-1}$ up to high temperatures. Therefore, many SOFC developers started their own sealing development. Most studies have been carried out on barium calcium aluminosilicate (BCAS) and barium calcium magnesium aluminosilicate (BCMAS). The comparison of BAS, CAS, and MAS glasses using B_2O_3 as a fluxing agent and TiO_2 , ZrO_2 , NiO , and Cr_2O_3 as a nucleating agent showed that the barium glass tended to react with chromium steel more than the other glasses, showed a faster crystallization, and an appropriate thermal expansion (Lahl *et al.*, 2000, 2002; Tulyaganov *et al.*, 2013). These materials can however interact forming BaCrO_4 in the presence of oxygen. For these reasons, different other compositions have been considered, such as the ones belonging to the $\text{Na}_2\text{O}\text{--}\text{SiO}_2$ system or diopside (Lin *et al.*, 2018) or $(\text{CaMgSi}_2\text{O}_6)$ – alkali one (Sabato *et al.*, 2019). Compatibility studies between steels and glasses clearly showed that the sealing material alone does not lead to a good joining. It is more important to adopt the interconnect/sealant couple. Under oxidizing conditions, the formed oxide scales of ferritic steels (chromium oxide scale at the inner interface to the steel followed by a scale of manganese chromium spinel at the outer interface toward the glass) are partially dissolved by the glass. This leads, on the one hand, to a good adhesion and sticking between sealant and steel, on the other hand, however, to a destabilization of the steel at the three-phase boundary glass/metal/air. Thus, good sticking and stability against corrosion may become conflicting objectives. As already mentioned, besides glass-ceramics, compressive seals and brazing systems have also been investigated (Fergus, 2005). In the case of compressive seals, metallic gaskets and mica-based materials (vermiculite, phlogopite) were tested. All seals are not hermetically gastight and require high mechanical loads for reaching low leakage rates. The latter greatly affects the mechanical stability of the cell: other than an higher mechanical resistance the high load requires an extremely flat cell therefore decreasing the level of warpage tolerated. To date, no stack has been successfully operated with such sealing systems. Also, the brazing has not yet reached a reliably applied status, but the use of $\text{Ag}\text{--}\text{CuO}\text{--}\text{Ti}$ brazes in combination with an insulating layer seems to offer technologically interesting alternatives to the glass-ceramic sealants (Weil *et al.*, 2005).

Remaining Issues/Technological Hurdles to Be Solved

During the recent decade, much progress has been made to bring SOFC systems to application and market. The selection of the material plays a crucial role to determine the performance and the reliability of the SOFC technology and needs to be further improved. Good advancements in this respect have been obtained through the development of more efficient and cheaper SOFC, lowering the operating temperature, widen the range of application and increase the durability. The production of thin film structures improves the overall cell performance and electrolyte conductivity leading to systems working at temperature below 600°C supported by metal interconnects (MS-SOFC). The use of metal supports with different material compositions, trace element doping and the deposition of protecting layers by means of advanced manufacturing techniques, pushed the MS-technology towards commercialization. MS-SOFCs have a great potential to be applied as vehicle Auxiliary Power Units (APUs), particularly in the $600\text{--}650^\circ\text{C}$ operation temperature (Krishnan, 2017) that is, up to now, the great balance between production costs and performances. Even if the technology is in the verge of final commercialization, there is still need of material development especially in terms of sealants and reducing the use of rare earth materials. Finally, much more work is needed to push the development of protonic SOFC in terms of cell, interconnector and sealing materials toward more practical applications.

Introduction

The past decade has brought a growing interest in energy storage and renewable energy sources such as rechargeable batteries and solar cells to meet the increasing energy demands of a wide-range of devices, in particular smaller scale electronic devices, such as portable personal electronics and micro-electromechanical systems (MEMS). To accommodate this demand, it is essential to develop small-scale energy storage systems. Many techniques have been applied to manufacture small-scale energy storage systems, such as thin-film, stretchable and three-dimensional (3D) batteries (Sun *et al.*, 2013; Mazor *et al.*, 2012; Wang *et al.*, 2011; Bates *et al.*, 2000). Among many techniques utilized to date, laser-based process techniques, such as laser-induced forward transfer (LIFT), pulsed laser deposition (PLD) and laser surface modification (LSM), have been proposed as practical approaches to integrate various types of micropower sources, such as thin-film microbatteries, ultracapacitors, and solar cells for small scale electronic devices.

Lasers are a versatile tool that delivers energy at selected locations with a laser beam size of several microns, thus allowing microscale processing of materials. One of the key advantages in lasers is their direct-writing capability that can eliminate expensive photolithographic patterning processes in many device fabrications, thus lowering the manufacturing cost (Arnold *et al.*, 2007; Hon *et al.*, 2008; Piqué and Chrisey, 2001; Roy, 2007; Serra and Piqué, 2019). Furthermore, since photons can be absorbed near the surface region, laser light is an ideal tool for surface modification without damaging the substrate underneath, thus allowing the use of plastic substrates for flexible devices. Recently, three-dimensional (3D) electrodes have been proposed to enhance the power density in microbatteries while the high energy density of these systems is maintained (Ferrari *et al.*, 2015; Jeyaseelan and Rohan, 2009; Oudenhoven *et al.*, 2011). Laser processing techniques can be utilized to manufacture these 3D electrodes for Li-ion microbatteries (Ferrari *et al.*, 2015). In addition, laser processing techniques can also be utilized to embed the battery components into the device package, which can reduce the device size and weight (Sutto *et al.*, 2006). Therefore, the future of laser processing techniques for manufacturing micropower sources looks very promising. This chapter will provide a brief review of LIFT techniques used for fabricating ultracapacitors and thick-film microbatteries, PLD techniques used for fabricating thin-film microbatteries, and LSM processes used for 3D electrode microbatteries. Lastly, we will discuss challenges and future of laser processing techniques to develop advanced energy storage systems.

Laser-Induced Forward Transfer Techniques

Laser induced forward transfer (LIFT) is an additive direct write technique that allows high-resolution printing of complex materials from a donor film to a receiver substrate using a pulsed laser beam. Fig. 1 shows a schematic illustration of the basic components of the LIFT system. A pulsed laser beam is used to induce the printing of material from a donor film onto a receiver substrate. The donor film is prepared on a laser-transparent quartz wafer by applying the material to be transferred. The receiver substrate is placed on the x-y stage, facing the donor film separated by a distance of 50–1000 μm . Laser beam is focused on the backside of the donor film by a microscope objective. Upon absorbing the incident laser pulse above the threshold energy, material is ejected from the donor film and transferred toward the receiver substrate. The laser fluences of 10–100 mJ cm^{-2} are typically used for LIFT of battery materials. In comparison with other printing techniques, LIFT processes can be performed at ambient conditions without using clean-room environments or vacuum.

One important feature of the LIFT process for battery materials is that the printed materials typically show porous structures. These porous structures are an essential feature for batteries due to an increased contact area for the electrolyte permeating the active electrode materials, leading to improved charge transfer and accordingly an enhancement in utilization of the electrode materials. Another important feature of the LIFT printing in comparison to inkjet printing is the former's suitability to print high viscosity nanoinks due to its nozzle-free nature (Piqué *et al.*, 2008; Duocastella *et al.*, 2012). Despite its simplicity, inkjet printing is limited to printing only low viscous inks to avoid clogging of the dispensing nozzles (Calvert, 2001). Thus, LIFT printing of high viscosity pastes enables a wide range of applications such as 3D interconnects, metamaterials, free-standing structures, and circuit repairs (Auyeung *et al.*, 2009; Auyeung *et al.*, 2011; Kim *et al.*, 2010, 2013; Mathews *et al.*, 2013; Piqué *et al.*, 2008, 2013; Wang *et al.*, 2010a). In this section, we will discuss the LIFT printing of active electrodes in energy storage systems, such as batteries and capacitors.

Laser Printing of Thick Film Electrodes

Lasers have been used to print thick-film electrodes for alkaline and Li-ion microbatteries (Kim *et al.*, 2007, 2012, 2014; Ollinger *et al.*, 2006a,b; Piqué *et al.*, 2004; Wartena *et al.*, 2004). Compared to sputter-deposited thin-film electrodes, laser-printed thick-film electrodes produce much higher capacities per electrode area. This enhanced cell performance is related to the previously mentioned porous structures of the laser printed electrodes because this porosity allows improved Li-ion diffusion across the

Fig. 1 A schematic illustration of the laser-induced forward transfer (LIFT) setup.

electrodes without a significant internal resistance loss. Kim *et al.* (2007) used a ns-laser ($\lambda = 355$ nm) to print both thick-film electrodes (LiCoO_2 cathode and carbon anode) for Li-ion microbatteries and studied their electrochemical properties. In this work, the laser-printed electrodes were separated by a laser-cut porous membrane that was soaked with a gel polymer electrolyte to build mm-size solid-state packaged Li-ion microbatteries. Fig. 2(a) and (b) shows a cross-sectional schematic diagram and an SEM image of a typical Li-ion microbattery printed by LIFT.

It is important to produce thicker electrodes for achieving high charge/discharge capacity in Li-ion microbatteries. One important feature of LIFT is that the thickness of the printed films can be easily controlled by changing the number of printing passes. As seen in Fig. 2(c), the thickness and mass of the LiCoO_2 cathodes can be linearly increased with the number of LIFT printing passes. Accordingly, the charge/discharge capacity can also be increased with the cathode film thickness (up to $115\ \mu\text{m}$ thick). (See Fig. 2(d)). In this case, a porous structure with high surface areas allows better ionic and electronic transport through the thick electrodes ($\sim 115\ \mu\text{m}$) with small internal cell resistance. In addition, these thick film microbatteries also exhibit a fast discharge rate, which is important for high-power density device applications. The cell with a $68\ \mu\text{m}$ thick LiCoO_2 cathode provides a maximum density of $38\ \text{mW cm}^{-2}$ at a discharge rate of $10\ \text{mA cm}^{-2}$. It is useful to compare the battery performances (discharge capacities per active electrode area) of LIFT-printed thick-film electrodes with those made by sputter-deposited thin-films. Typical sputter-deposited thin-film electrodes (thickness = $2.5\ \mu\text{m}$, active area = $1\ \text{cm}^2$) produce a discharge capacity of $160\ \mu\text{Ah cm}^2$ at a discharge rate of $100\ \mu\text{A cm}^2$ (Bates *et al.*, 2000) while the LIFT-printed thick-film electrodes (thickness = $115\ \mu\text{m}$, active area = $0.49\ \text{cm}^2$) produce a discharge capacity of $\sim 2600\ \mu\text{Ah cm}^2$ at the same discharge rate. Although the volumetric capacity is three times smaller than that of the sputter-deposited electrodes, the laser-printed thick film microbatteries can deliver orders of magnitude higher discharge capacity per active electrode area. Thus, the laser-printed thick film microbatteries might be suitable for small portable electronics where limited space is available for the power source.

Compared to lithium-ion batteries, lithium-sulphur batteries can deliver a much higher theoretical discharge capacity ($1675\ \text{mAh g}^{-1}$), which is an order of magnitude higher than that of olivine LiFePO_4 electrode ($170\ \text{mAh g}^{-1}$). Rosenberg and Hintennach (2013) fabricated lithium-sulphur based electrodes by LIFT using a XeCl excimer laser ($\lambda = 308$ nm). In this design, electrodes were prepared by three printing steps: First, a carbon binder mixture was printed on the substrate, then the sulphur was printed onto the carbon layer, and finally a thin carbon layer was printed to fully cover the sulphur materials within carbon matrix. The thickness of all three layers was $\sim 60\ \mu\text{m}$. The cells based on these laser-printed electrodes were cycled galvanostatically between 1.0 and 3.0 V versus Li/Li^+ and exhibited a remarkably high discharge capacity as high as $\sim 1200\ \text{mAh g}^{-1}$ at the 1 C current rate and a 79% capacity retention after 400 cycles.

Laser Printing of Solid State Electrolytes

Typical Li-ion battery systems consist of a lithiated metal oxide cathode, a lithium metal (or carbon/graphite) anode, and a lithium ion conducting membrane soaked with a liquid electrolyte. A liquid electrolyte is commonly utilized in commercial Li-ion

Fig. 2 (a) Cross sectional schematic diagram (not to scale) of a typical Li-ion microbattery. (b) Cross sectional SEM micrograph of a packaged thick-film Li-ion microbattery. (c) LiCoO₂ Cathode thickness vs. Cathode mass as a function of the number of LIFT passes. (d) Voltage vs. capacity per unit area for a Li ion microbatteries with different thicknesses of LiCoO₂ Cathodes. Reprinted Kim, H., Auyeung, R.C.Y., Piqué, A., 2007. Laser-printed thick-film electrodes for solid-state rechargeable Li-ion microbatteries. *J. Power Sources* 165, 413–419. Copyright (2007), with permission from Elsevier.

batteries due to its high ionic conductivity. Recently, there is a strong interest in developing all-solid state battery, which utilizes a solid-state electrolyte since the use of liquid electrolyte may cause safety and leakage issues. LIFT process was used to print a solid-state electrolyte membrane for Li-ion microbatteries (Ollinger *et al.*, 2006a,b). This solid state electrolyte membrane offers some important advantages in comparison to a liquid electrolyte. It provides a proper strength and flexibility of the co-polymer matrix, while exhibiting the proper electrochemical behaviour for ionic liquids with an ionic conductivity of 1–3 mS cm⁻¹. Thus, the laser-printed solid electrolyte membrane can serve as both the separator and the electrolyte. Fig. 3(a) shows the optical image of laser-printed solid-state membrane on a glass substrate. This membrane was dried at 75°C for 1 h creating a continuous flexible pinhole free membrane. As shown in Fig. 3(b), it is flexible enough to be lifted from the glass substrate using tweezers without breaking the membrane. Fig. 3(c) shows the charge/discharge cycles of a Li-ion microbattery prepared with the 20 μm thick laser-printed solid-state membrane, the Li-metal anode and the 30 μm thick LiCoO₂ cathode. This battery was charged/discharged at 40 μA cm⁻² and exhibited a discharge capacity of 495 μAh cm⁻² with a coulomb efficiency of 98% after the 4th cycle. However, the coulomb efficiency of this battery decreased below 50% after 100 cycles. Thus, more investigations are necessary to further improve the battery performance for “all laser-printed batteries” based on the solid-state electrolyte membrane.

Laser Printing of Ultracapacitors

Ultracapacitors, also known as supercapacitors, are electrochemical energy storage and power generation devices that show electrochemical properties similar to both batteries and capacitors. Similar to batteries, ultracapacitors can store a large amount of energy during charging state and similar to capacitors, they can discharge very high power density in a very short time. Hydrous ruthenium oxide has been proposed as an excellent electrode for ultracapacitors because rapid insertion and release of electrons and protons can occur in this material due to its high specific surface area (Sarangapani *et al.*, 1996). One of the advantages in LIFT is that it can print complex ink composed of the electrode material and relevant electrolyte. Arnold *et al.* (2002) fabricated a planar type of hydrous ruthenium oxide ultracapacitors by printing a composite ink composed of ruthenium oxide and electrolyte. As shown in Fig. 4(a) and (b), ultracapacitors were printed on 1 cm² gold-coated quartz substrate using LIFT technique and then they were laser micromachined into four electrically isolated cells. The charge/discharge curves for these ultracapacitors are shown in Fig. 4(c). The ultracapacitors delivered the linear charge/discharge behaviour at constant current rates, suggesting ideal capacitor behaviour. These ultracapacitors connected in series and parallel combination can be discharged at high current rate (> 50 mA) for delivering the proper additive values (see Fig. 4(d)) (Arnold *et al.*, 2003).

Fig. 3 Optical images of (a) the laser-printed solid-state membrane on a glass substrate and (b) membrane partially lifted off of glass substrate by tweezers. (c) Charge-discharge performance of a packaged Li microbattery (LiCoO₂/solid electrolyte membrane/Li) cycled between 4.2 and 3 V at current density of 40 μA/cm². The battery was tested in air at 25°C. The active electrode area is 1 cm². Reprinted from Ollinger, M., Kim, H., Sutto, T.E., Piqué, A., 2006a. Laser direct-write of polymer nanocomposite. *Appl. Sur. Sci* 252, 8212–8216. Copyright (2006), with permission from Elsevier.

In summary, LIFT is a powerful technique for printing thick films for microbatteries and ultracapacitors. Thick-film electrodes (cathodes and anodes) with high discharge capacities were fabricated by LIFT printing for microbatteries. LIFT process was also used for printing solid state electrolyte membranes with an ionic conductivity of 1–3 mS cm⁻¹.

Pulsed Laser Deposition Techniques

Pulsed laser deposition (PLD) is a physical vapor deposition (PVD) technique that allows high quality thin film deposition of materials in a vacuum chamber using a high power pulsed laser beam. Fig. 5 shows a schematic illustration of the basic components of the PLD system. A high power pulsed laser beam is focused inside a vacuum chamber onto the target which is typically rotated to avert its fast deterioration and maintain its surface under approximately constant conditions. Upon laser irradiation, the target material is vaporized and creates a plasma plume that expands from the target to the substrate, producing a thin film on the substrate. The target-substrate distance can be adjusted between 4 and 10 cm. Key parameters that can affect the film properties are laser fluence, substrate temperature and oxygen partial pressure. Furthermore, the use of lattice matched substrates with the film is also important to grow epitaxial thin films with preferred orientations.

PLD process for thin film growth has some important advantages over other PVD processes: (1) PLD process can occur at dynamic range of chamber pressures from ultrahigh vacuum (UHV) to very high pressures (up to beyond 1 Torr) and in any kind of background gas, such as oxygen or argon. (2) It can grow multilayer thin films using a multi-target carousel system since the laser beam can be alternatively focused over two or more targets. This capability is well suited for manufacturing complex stacks, such as layered battery structures. (3) It allows a congruent transfer of the composition between the target and the film. This is attributed to the extremely high heating rates on the target surface due to its strong interaction with the laser irradiation. When the laser fluence is increased above the ablation threshold where the absorbed laser energy becomes higher than that needed for evaporation, the flux of vaporized species is not dependent on the vapor pressures of the target constituents. This nonequilibrium process leads to the congruent evaporation of the

Fig. 4 (a) Micromachining to produce a planar $\text{RuO}_2\cdot 0.5\text{H}_2\text{O}$ micro-ultracapacitor. (b) Picture laser machined planar micro-ultracapacitors on gold-coated quartz substrate. target material. It is very difficult to achieve this stoichiometric transfer between target and substrate from other PVD processes such as sputtering or e-beam. The electrochemical properties of pulsed-laser deposited thin film electrodes (cathodes, anodes and solid electrolytes) for lithium ion microbatteries will be discussed in this section.

Method of preparation	Kinetic energy (eV)	Crystallization temperature	Heat-treatment	References
PLD	10–100	300–600°C	In-situ heating No post-annealing	(Julien <i>et al.</i> , 2001; Xia <i>et al.</i> , 2006)
Sputtering	5–10	700–800°C	In-situ heating Post-annealing	(Bates <i>et al.</i> , 2000; Kim, 2004)

PLD of Cathode Thin Films

Recently, thin film Li-ion microbatteries have received increasing interests due to their potential applications as micropower sources for small scale devices such as micro-sensors and implantable medical sensors. PLD technique has been used to fabricate various cathode thin films for Li-ion microbatteries, including LiCoO₂, LiNiO₂, LiNi_{0.8}Co_{0.2}O₂, LiMn₂O₄, Li(NiMnCo)O₂ and LiFePO₄. In Li-ion microbatteries, an ideal thin-film cathode is a well-crystallized, layered structure of lithiated oxides. Thus, a post deposition annealing process at relatively high temperatures is commonly used to achieve good film crystallinity. However, this high temperature annealing step often creates microcracks in the lithiated films that cause a shorting problem in thin-film microbatteries. Furthermore, this high temperature annealing also damages the current collecting layers and substrate underneath the cathode films. One of advantages in PLD grown thin films is that the film can be crystallized at relatively low temperatures compared to those grown by other PVD techniques. This is because the kinetic energy (10–100 eV) of the ejected species in the laser-induced plasma plume is much higher than those from other PVD techniques, such as sputtering (5–10 eV) and evaporation (<1 eV) (Eason, 2006; Chrisey and Hubler, 1994). As shown in Table 1, LiCoO₂ cathode thin films fabricated by sputtering require a post deposition annealing (700–800°C) (Bates *et al.*, 2000; Kim, 2004) to achieve better crystallized films, while the same cathode thin films grown by PLD can be crystallized at temperatures (300–600°C) without any postdeposition annealing. Kuwata *et al.* (2006) reported that PLD-grown LiCoO₂ thin films become well-crystallized structures with a high density and smooth surface morphology without sign of cracks, thus essential for high performance in thin film batteries. Julien *et al.* also fabricated the well-crystallized LiCoO₂ thin films with a single layered structure at 300°C.

The crystallographic orientation is also important parameter to affect the electrochemical activity of the cathode thin films. In general, highly oriented thin films can easily be formed by PLD process due to a layer-by-layer growth mode of the PLD films (Chrisey and Hubler, 1994). Xia and Lu (2007) fabricated LiCoO₂ cathode thin films by PLD and the results showed that the (003) preferred orientation leads to reduced Li-ion diffusivity while the (101) and (104) orientations tend to increase the Li-ion diffusivity. The substrates also play an important role to determine the microstructure of the cathode thin films. For example, LiNi_{0.5}Mn_{0.5}O₂ cathode thin films were grown by PLD technique on two different substrates (Au and stainless-steel) and the results showed that the films grown on stainless-steel formed along a spinel structure due to a severe interdiffusion between the film and the substrate during high temperature deposition process, while the films grown on Au substrate showed a layered structure. The battery based on LiNi_{0.5}Mn_{0.5}O₂ cathode thin film on the Au substrate exhibited a reversible capacity of ~150 mAh g⁻¹, which is four times higher than that of the stainless-steel substrate (40 mAh g⁻¹) (Xia *et al.*, 2008).

Even though the film stoichiometry is normally close to the target stoichiometry in PLD, it is not necessarily true in the case that the targets consist of volatile light elements such as lithium (Simmen *et al.*, 2008). If a target contains lithium, this light element can be easily scattered by background gas molecules in the laser-induced plasma plume or be ejected by energetic species arriving at the film surface during PLD process. Thus, the lithium content in the deposited film tends to be lower than the target. This lower lithium content in the film will cause structural changes and impurity formation and eventually degrade the battery performance. Simmen *et al.* (2008) fabricated LiMn₂O₄ cathode thin films with a desired lithium content by PLD using a Li-excess composite target and achieved a discharge capacity of ~42 μAh cm⁻² μm⁻¹. LiCoO₂ cathode thin films were also fabricated by PLD using a target containing 15% excess Li₂O content with a reasonably good discharge capacity (50–60 μAh cm⁻² μm⁻¹) (Xia and Lu, 2007).

Vanadium oxide thin films have been used as cathode material of Li-ion batteries due to its large theoretical specific capacity (V₂O₅, 147 mAh g⁻¹) (Mauger and Julien, 2018). One advantage of vanadium oxide is that crystalline V₂O₅ films can be grown by PLD at a relatively low temperatures as low as 200°C. Madhuri *et al.* (2002) reported that highly c-axis orientated crystalline V₂O₅ cathode thin films were successfully synthesized on ITO-coated glass substrate by PLD at relatively low temperatures as low as 200°C. Recently, amorphous vanadium oxides (a-VO_x) thin films are becoming a popular cathode material for Li-ion-ion batteries because a-VO_x can offer shorter diffusion paths and thus can deliver high discharge capacity in comparison to crystalline VO_x counterparts. PLD has been successfully utilized for manufacturing a-VO_x thin films on stainless steel substrates from V₂O₅ target in the oxygen partial pressures of 0–30 Pa (Petnikota *et al.*, 2018). The cells based on these V₂O₅ cathode thin films exhibited a reversible specific capacity as high as 300 mAh g⁻¹ at the C/10 current rate and a 90% capacity retention after 100 cycles. Table 2 shows the electrochemical properties of various cathode thin films fabricated by PLD.

PLD of Anode Thin Films

Amorphous silicon (a-Si) thin films have been widely studied as a potential anode for Li-ion batteries due to its large theoretical capacity (Li₂₂Si₅, 4200 mAh g⁻¹). Although there is a huge volume expansion (>300%) during lithiation, Xia and Lu (2007)

successfully deposited a-Si thin films on stainless-steel substrates at room temperature by PLD for thin film microbatteries. The cells based on the a-Si thin films (120 nm thick) exhibited a stable discharge capacity of $\sim 50 \mu\text{Ah cm}^{-2}$ between 0.1 and 1.5 V at a current density of $100 \mu\text{A cm}^{-2}$ for 50 charge/discharge cycles with a small capacity fade rate (0.2% per cycle). Thus, the a-Si thin film anode can effectively minimize the volume expansion during lithiation process and result in an improved capacity retention compared to the crystallized silicon (c-Si).

Recently, there have been many efforts on developing Si-based composite anodes by combining the Si with carbon-based components such as single-wall carbon-nanotube (SWCNT) and multilayer graphene (MLG). (Biserni *et al.*, 2015; Chou *et al.*, 2010; Radhakrishnan *et al.*, 2013). For example, Chou *et al.* fabricated Si-SWCNT composite anodes by depositing Si film onto SWCNT paper at room temperature by PLD. The cell based on the a-Si/SWCNT composite anode exhibited a specific capacity of 163 mAh g^{-1} at a current rate of 25 mA g^{-1} , which is more than 60% improvement of the pristine CNT paper (Chou *et al.*, 2010). Radhakrishnan *et al.* (2013) fabricated Si-MLG composite anodes for Li-ion batteries by depositing ultra-thin Si layers onto a MLG-coated Ni foam substrate using PLD. The MLG layer grown by CVD serves as a conducting platform, thus helping to avoid contact losses from volume expansion during lithiation processes of the Si anode, while the Ni foam serves as a current collector as well as provides a larger surface area in comparison to thin metal foils. Electrochemical test results on the Si-MLG composite anodes showed a stable specific capacity of 2400 mAh g^{-1} during the cycling test, whereas the cells based on the pure Si anodes exhibited a fast fading capacity after 1st cycle due to the volume expansion. Biserni *et al.* (2015) fabricated Si-C composite anodes by depositing $1 \mu\text{m}$ -thick porous a-Si layer on copper foils at room temperature by PLD, followed by CVD of carbon layers. In this design, the porous nanostructure of Si film accommodates the volume expansion, while the disordered carbon layer promotes the formation of a stable solid electrolyte interface (SEI) layer and protects the Si from direct contact with the electrolyte. Electrochemical test on these Si-C composite anodes showed a specific capacity of $\sim 75 \mu\text{Ah cm}^{-2}$ after 1000 cycles at a current rate of $540 \mu\text{A cm}^{-2}$. Moreover, the capacity of this composite anode can be improved to $\sim 175 \mu\text{Ah cm}^{-2}$ by thickening the Si thickness to $2.5 \mu\text{m}$.

Due to a relatively small volume change ($<0.2\%$) during charge/discharge cycles, spinel lithium titanate ($\text{Li}_4\text{Ti}_5\text{O}_{12}$) has been considered as a good anode material for Li-ion batteries. This anode exhibits a theoretical specific capacity of 175 mAh g^{-1} and a large voltage plateau at 1.55 V during charge/discharge profiles. One drawback of $\text{Li}_4\text{Ti}_5\text{O}_{12}$ is a poor electrical conductivity, which limits their application. Deng *et al.* (2009) fabricated $\text{Li}_4\text{Ti}_5\text{O}_{12}$ anode thin films on Pt/Ti/SiO₂/Si substrates at room temperature by PLD using a KrF excimer laser (248 nm). Annealing the as-deposited films at temperatures of $600\text{--}800^\circ\text{C}$ improved the charge/discharge capacity. Fig. 6 shows the charge discharge curves for $\text{Li}_4\text{Ti}_5\text{O}_{12}$ anode films at a current rate of $20 \mu\text{A cm}^{-2}$ between 1 and 2 V. These anode thin films exhibited a charge-discharge plateau at $\sim 1.55 \text{ V}$ (Fig. 6(a)) and a discharge capacity of 149 mAh g^{-1} after 30 cycles (Fig. 6(b)). Amorphous LiNiVO_4 anode thin films were also grown by PLD using a Li-excess target ($\text{Li}_{1.2}\text{NiVO}_4$) for thin film microbatteries (Tang *et al.*, 2006). The cells based on these anode thin films showed a reasonably good battery performance with a discharge capacity of $410 \mu\text{Ah cm}^{-2} \mu\text{m}^{-1}$ after 50 cycles. Table 3 lists the electrochemical properties of various cathode thin films fabricated by PLD technique.

PLD of Solid Electrolyte Films

In order to develop all solid-state thin-film batteries, thin films of solid-state electrolytes with high ionic conductivity and low electronic conductivity are required. PLD technique has been successfully employed to fulfil these requirements in growing thin films of various solid-state electrolytes, such as lithium phosphorous oxynitride (LIPON) (Zhao *et al.*, 2002), $\text{Li}_{2.2}\text{V}_{0.54}\text{Si}_{0.46}\text{O}_{3.4}$ (LVSO) (Kuwata *et al.*, 2004; Zhao and Qin, 2003), $\text{Li}_4\text{SiO}_4\text{--Li}_3\text{PO}_4$ (Sakuda *et al.*, 2010), $\text{Li}_{3.25}\text{Ge}_{0.25}\text{P}_{0.75}\text{S}_4$ (thio-LISICON) (Ohta *et al.*, 2005), $\text{Li}_{0.5}\text{La}_{0.5}\text{TiO}_3$ (LLTO) (Ahn and Yoon, 2005), and $80\text{Li}_2\text{S--}20\text{P}_2\text{O}_5$ films (Sakurai *et al.*, 2011). Zhao *et al.* (2002) fabricated LIPON thin films on three different substrates (Si-wafer, Au/Si, and Al/glass) by PLD in an N_2 gas atmosphere using a Li_3PO_4 target. The ionic conductivity of $1.6 \times 10^{-6} \text{ S cm}^{-1}$ was observed from the LIPON thin films deposited under the optimum PLD conditions (200 mTorr of N_2 gas and a laser fluence of 15 J cm^{-2}). Kuwata *et al.* (2004) fabricated $\text{Li}_{2.2}\text{V}_{0.54}\text{Si}_{0.46}\text{O}_{3.4}$ (LVSO)

solid electrolyte thin films by depositing the films on quartz substrates by PLD and the LVSO films showed an ionic conductivity of $2.5 \times 10^{-7} \text{ S cm}^{-1}$. Ahn *et al.* fabricated $\text{Li}_{0.5}\text{La}_{0.5}\text{TiO}_3$ (LLTO) thin film electrolytes by PLD at 400–600 °C. The 360 nm-thick LLTO thin films showed an amorphous phase with an ionic conductivity of $2.0 \times 10^{-5} \text{ S cm}^{-1}$ at room temperature. The LLTO/ LiCoO_2 /Pt cells exhibited 63% capacity retention after 300 cycles (Ahn and Yoon, 2005). Table 4 lists electrical properties of various solid-electrolyte thin-films fabricated by PLD. The ionic conductivity of PLD-grown solid electrolyte thin films was observed in a range from 10^{-4} to $10^{-7} \text{ S cm}^{-1}$, while the electrical conductivity exhibited very low (10^{-7} – $10^{-14} \text{ S cm}^{-1}$). Thus, these PLD-grown solid electrolyte thin films are very promising for manufacturing solid state thin film microbatteries.

Recently, all solid state thin film microbatteries have attracted much attention due to their excellent potential for improving their safety and reliability compared to conventional lithium batteries containing flammable organic liquid electrolytes. PLD was successfully utilized to grow individual layers sequentially. Kuwata *et al.* (2004) fabricated all solid state thin film microbatteries, consisting of LiCoO_2 cathode, LVSO solid electrolyte, and amorphous SnO anode, by a sequential PLD process. These thin film microbatteries exhibited an initial capacity of $9.5 \mu\text{Ah cm}^{-2}$ and 45% capacity retention after 100 cycles at a current rate of $44 \mu\text{A cm}^{-2}$ between 0.01 and 3 V. Matsuda *et al.* (2018) also fabricated all solid-state microbatteries using an amorphous Li_3PO_4 solid electrolyte film by a sequential PLD process. Fig. 7(a) shows a cross sectional SEM image of a $\text{Li}/\text{Li}_3\text{PO}_4/\text{LiCoO}_2/\text{Pt}$ thin film microbattery, indicating a columnar-like LiCoO_2 cathode. As shown in Fig. 7(b), this microbattery exhibited excellent battery performances: discharge capacity of $97 \mu\text{Ah cm}^{-2}$ (or $44 \mu\text{Ah cm}^{-2} \mu\text{m}^{-1}$), which is 64% of the theoretical volumetric capacity of LiCoO_2 ($69 \mu\text{Ah cm}^{-2} \mu\text{m}^{-1}$).

In summary, PLD has been considered as an ideal technique for growing thin films of cathodes, anodes and solid electrolytes for thin film microbatteries. Well-crystallized and textured cathode thin films were fabricated by PLD due to their relatively low crystallization temperatures and good adhesion properties. PLD has been successfully utilized for growing anode materials such as amorphous silicon, silicon-based composite and $\text{Li}_4\text{Ti}_5\text{O}_{12}$ anodes. PLD-grown solid electrolyte thin films have been proved to exhibit good ionic conductivity (10^{-4} – 10^{-7} S cm^{-1}) and low electrical conductivity (10^{-7} – 10^{-14} S cm^{-1}). Lastly, a sequential PLD growth was used in the fabrication of all solid-state thin film microbatteries exhibiting reasonably good battery performance. In addition, due to increasing demand for flexible devices, manufacturing thin film microbatteries on flexible substrates such as polyimide (Kapton) would be highly desirable. On this matter, the use of PLD technique might be possible to grow active materials at low temperatures ($< 300^\circ\text{C}$) since films grown by PLD are usually crystallized at relatively low temperatures compared to other PVD techniques such as sputtering and e-beam.

Laser Surface Modification (LSM)

Lasers are widely used to modify the surface properties of renewable energy materials to improve their performance in photo-voltaic devices and power sources. Laser surface modification (LSM) has been applied extensively in the fabrication of solar cells. Recently, LSM for batteries has also been shown to improve the battery performance. This section reviews three LSM processes for Li-ion batteries: laser structuring, laser annealing and laser drying.

Laser Structuring for 3D Electrodes

Recently, the development of three-dimensional (3D) electrodes was proposed to enhance the discharge capacities while maintaining high power density of lithium microbatteries (Jeyaseelan and Rohan, 2009; Long *et al.*, 2004; Notten *et al.*, 2007; Oudenhoven *et al.*, 2011). However, increasing both energy density and power density simultaneously is very challenging issue due to the increased internal resistance. Lasers were successfully employed to texture various thin-film and thick-film electrodes to form 3D structures with improved Li-ion diffusion kinetics (Kim *et al.*, 2012; Kohler *et al.*, 2011, 2013; Pröll *et al.*, 2011, 2014). There are two different types of laser structuring processes: one is “self-organized structuring” process and the other is “direct

structuring” process. In general, the self-organized structuring process can be applied for thin film and thick film electrodes that have small electrode footprint areas such as microbatteries, while the direct structuring process can be applied for large area electrodes such as pouch cells (Pfleging, 2018).

The self-organized structuring process was applied for structuring LiCoO₂ cathode thick films ($\sim 30\ \mu\text{m}$ thick) using a KrF excimer laser ($\lambda = 248\ \text{nm}$) (Kim *et al.*, 2012). By adjusting laser fluences and number of laser pulses, self-organized conical microstructures were created on the film surface (see Fig. 8(b)). In this case, the structuring process can be explained by selective material ablation and consequent re-deposition of material. As shown in Fig. 8(c), the cell based on this laser-structured LiCoO₂ cathode thin film exhibited a discharge capacity of $\sim 70\ \text{mAh g}^{-1}$ after 100 cycles, which is two times higher than that of the unstructured thin film ($36\ \text{mAh g}^{-1}$). In this case, the enhanced discharge capacity is attributed to the improved Li-ion diffusion rate through 3D microstructures of the cathode. Although uniform surface texture can be achieved by an excimer laser ablation, the processing speed is very slow so that it can be used for small electrode area such as microbatteries.

For large area laser structuring processes, high power femtosecond (fs) lasers with high repetition rates were utilized to directly ablate the electrode materials to form 3D micro-grids (Park *et al.*, 2019; Pröll *et al.*, 2014; Smyrek *et al.*, 2016). The use of fs-laser pulses can minimize the damage to the cathode material near the ablated region resulting in uniformly distributed micro-grid structures, while minimizing the amount of material loss ($< 15\%$) during the process. For example, 3D micro-grid structures of LiNi_{0.5}Mn_{0.3}Co_{0.2}O₂ (NMC) cathodes with various film thicknesses (100–210 μm) were fabricated by a fs-laser ablation (Park *et al.*, 2019). Fig. 9 shows a schematic illustration of the laser structuring system. Fig. 10(a) shows SEM image of 3D micro grid structures of the laser-structured NMC thick film electrode (210 μm). As shown in Fig. 10(b), the groove was

formed over entire thickness of the electrode and no evidence of melting or re-solidification was observed, indicating little thermal effect during the laser structuring. Fig. 10(c) shows the normalized discharge capacity of the cells based on the unstructured and structured NMC thick films with various electrode thicknesses (100–210 μm) at different current rates (0.1–3 C). As the current rate increases, the discharge capacity of the unstructured electrode dropped quickly, while the laser-structured electrodes always showed higher capacity retentions than the unstructured electrodes. For example, the laser-structured NMC electrode (100 μm) showed 70% capacity retention at 3 C rate, which is one order of magnitude higher than the unstructured NMC electrode ($\sim 5\%$). These results suggest that laser-structured 3D electrodes are suitable for fast charging/discharging devices at a higher current rate.

Laser Annealing of Thin Film Electrodes

In general, annealing processes can improve the microstructures of the thin film electrodes and accordingly, increase the electrochemical performance of the electrodes. On the other hand, rapid thermal annealing can also form some cracks on the surface due to volume expansion and shrinkages. Laser annealing processes have been applied for improving the crystalline phases of thin-film electrodes such as LiCoO_2 and LiMn_2O_4 cathodes (Kohler *et al.*, 2011; Pröll *et al.*, 2014). Pröll *et al.* (2012) demonstrated that sputter-deposited Li–Mn–O thin films were annealed by a high power diode laser ($\lambda = 940 \text{ nm}$) to form a spinel like phase. The grain size of the as-deposited film was $< 10 \text{ nm}$ while the laser annealed film at 600°C for 2000 s showed the lateral grain sizes of $\sim 500 \text{ nm}$ (See Fig. 11(a) and (b)). As shown in Fig. 11(c), a spinel-like Li–Mn–O phase can be obtained under the optimized laser annealing conditions ($T = 680^\circ\text{C}$ for 100 s), showing the typical bands of Mn–O compounds at 629 cm^{-1} (A_{1g} species). Similar Raman spectra could be observed for slightly lower annealing temperature of $T = 600^\circ\text{C}$ with a longer annealing time ($t = 2000 \text{ s}$) (Fig. 11(c)). Cyclic voltammetry (CV) scans showed two redox peaks for spinel thin films, indicating that the annealed films were well crystallized and intercalation processes were reversible (Fig. 11(d)).

Fig. 11 SEM images of Li-Mn-O films: (a) as-deposited and (b) laser annealed for $t = 2000$ s at $T = 600$ °C. Laser annealing processes were performed under ambient air. (c) Raman spectra of Li-Mn-O thin films with various annealing temperatures and times. Raman spectra of the spinel LiMn_2O_4 reference and of the as-grown film are added for comparison. Diode laser heat treatment of lithium manganese oxide films. *Appl. Surf. Sci.* 258 (12), 5146–5152. Copyright (2012), with permission from Elsevier.

Laser Drying of Thick Film Electrodes

One important step in battery manufacturing processes is a drying process for wet thick film electrodes. Typically, thick film electrodes (cathodes and anodes) are prepared from the slurry that consists of active material powders, conductive graphite, binders, solvents and some organic additives. Once the slurry is applied on the current collector by tape casting, this wet electrode must be dried with hot air or thermal radiation in order to improve the film adhesion (Günther *et al.*, 2016). It was reported that rapid drying using infrared radiation can cause a separation of active particles and binders, thus affecting adhesion of electrode on the current collector. Vedder *et al.* (2016) developed a laser-based drying process of water-based battery electrodes (LiFePO_4 cathodes and graphite anodes) using a fibre laser ($\lambda = 1070$ nm). By laser drying of these electrodes, coin cell capacity of 355 mAh g^{-1} can be achieved. In comparison to conventional oven drying process, this laser drying process could save the energy consumption by 50%. The laser drying speed of $50 \text{ cm}^2 \text{ s}^{-1}$ was achieved so far while further improvement might be possible using high power lasers. However, since the fast drying of electrodes with high power lasers may cause crack formation, careful optimization of process conditions will be required for upscaling of the laser based drying process technique.

In summary, LSM processes have been used as a useful tool for structuring thin film and thick film electrodes to form 3D electrodes for high-power and high-energy lithium-ion batteries. Well-crystallized cathode thin films were produced by the laser annealing process. In addition, the electrolyte wetting process is also important step in battery manufacturing since the process takes few hours to couple of days to achieve complete electrolyte impregnation. It was reported that laser structuring of the electrodes accelerated the wetting process by at least one order of magnitude, thereby reducing the manufacturing cost (Habedank *et al.*, 2019).

Challenging Issues and Outlook

Although laser-based processing techniques have been widely used in energy storage systems, there are some challenging issues in these techniques. The first challenging issue is developing reliable packaging processes for batteries. It is necessary that all active

components be sealed using the minimum weight and volume possible. For instance, many microelectronic devices may not allow the use of coin cells as their power sources due to their larger volume size yet limited capacity. In these cases, it might be possible to design microbatteries to be embedded on a chip. Since lasers can also be used to micromachine the chip surface to fabricate the pockets for embedded microbatteries and then directly print the battery components onto the devices via LIFT, laser processes are likely to play an important role in advanced microelectronic devices in the near future.

Second, for the integration of microbatteries into the other microdevices on a chip, high quality solid-state electrolytes must be developed. Although LIFT and PLD processes were used for manufacturing solid state electrolytes, the ionic conductivity of these electrolytes is much lower compared to liquid electrolytes, resulting in lower battery performance. Thus, improved solid state electrolytes must be developed in the near future.

Finally, the thickness of PLD grown electrodes must be increased in order to achieve larger discharge capacities in thin film microbatteries. In general, typical thickness of PLD-grown thin film electrodes is less than 3 μm because the cell resistance increases with the electrode thickness. This limited thickness issue can be solved by co-depositing conductive carbon and/or other active electrode materials. For this purpose, PLD processes can be used to deposit these composite electrodes by alternatively ablating carbon and electrode targets. These carbon-containing composite electrodes will be helpful to increase the electrode thickness beyond 3 μm and thus, achieve large discharge capacity with a minimum cell resistance loss.

Summary

Three laser-based processing techniques (LIFT, PLD and LSM) for the fabrication of energy storage devices have been reviewed. First, the LIFT technique has been demonstrated to print thick film electrodes and solid-state electrolyte membranes for Li-ion microbatteries and ruthenium oxide/electrolyte composite materials for planar ultracapacitors. The microbatteries fabricated with LIFT-printed thick film electrodes exhibited a high discharge capacity ($\sim 2600 \text{ mAh cm}^{-2}$), which is an order of magnitude higher than those of the sputter-deposited thin film electrodes. The LIFT process was also proposed to sequentially print all battery components (cathode, solid-state electrolyte and anode) to prepare all solid-state Li-ion microbatteries, which can be integrated into other microdevices on a chip. Secondly, the PLD technique was demonstrated as a practical tool to deposit numerous cathodes, anodes, and solid-state electrolytes for thin film microbatteries. Since PLD films can be crystallized at relatively low temperatures, well-crystallized, highly textured electrodes can be produced by PLD at lower temperatures compared to the sputter-deposited thin film electrodes. Moreover, the PLD technique was also successfully utilized to fabricate all solid-state thin film microbatteries by depositing all components sequentially. Thirdly, the LSM process was successfully applied to produce 3D architectures on various thin-film and thick-film electrodes for Li-ion microbatteries with improved battery performance including increased capacity retention and fast discharge rate.

In general, these laser-based processes can be utilized to integrate energy storage systems into other microdevices on a chip at various stages of the device fabrication steps. For instance, PLD can be used at the beginning of the device fabrication step since the deposited films may need to be patterned for devices, while LIFT printing can be applied at any stage of the device fabrication steps due to its direct-write additive capability. Hence, LIFT printing of a microbattery for a certain device might occur even after the device has already been fabricated. Lastly, the LSM process can be applied at any point of the device fabrication steps as well as it can be applied to selected locations on a device across a wide range of scales. Therefore, these laser-based processing techniques offer great potential for the manufacture of next generation embedded energy storage devices.

Introduction

Electroceramics, III-nitride semiconductors, including aluminum nitride (AlN), gallium nitride (GaN), and indium nitride (InN), are highly promising building blocks for solid-state optoelectronics and high-power electronics (Strite and Morkoç, 1992). In general, the III-nitrides have wurtzite crystal structure at ambient conditions, and the direct bandgap changes from 6.2 eV of AlN, 3.4 eV of GaN, to 0.7 eV of InN. Their ternary alloys such as aluminum gallium nitride (AlGaIn) and indium gallium nitride (InGaIn) provide the possibility of tuning the bandgaps continuously spanning from the deep ultraviolet (UV) into the whole visible spectrum. Till now, the III-nitrides are showing large amount of commercialized optoelectronics devices, including light-emitting diodes (LEDs) (Nakamura *et al.*, 1993; Funato *et al.*, 2006; Iso *et al.*, 2007), laser diodes (LDs) (Nakamura *et al.*, 1998a,b), UV photodetectors (Pernot *et al.*, 2000; Chen *et al.*, 1997; Muñoz *et al.*, 1997), and solar cells (Neufeld *et al.*, 2008; Jani *et al.*, 2007; Jiang *et al.*, 2017), which are widely applied in energy harvesting and saving.

AlN, GaN and InN are typically crystallized as a thermodynamically stable phase - wurtzite (space group is $P6_3mc$ (C_{6v}^4)), a metastable zinc-blende structure (space group is $F43m$ (T_d^2)), and a rock-salt structure at high-pressure phase transition (Strite and Morkoç, 1992; Morkoç, 2001). Moreover, III-nitrides have a large dielectric breakdown field and excellent electron transport properties (*e.g.*, the high mobility and large saturated drift velocity) that are very suitable for high-power, high-frequency electronic applications. And the main focus is AlGaIn/GaN based high-electron-mobility transistor (HEMTs) (Mishra *et al.*, 2002; Liu *et al.*, 2017; Yong *et al.*, 2005; Palacios *et al.*, 2005; Hu *et al.*, 2009). Due to the unique characteristics such as high-temperature stability and low sensitivity in radiation, it makes III-nitrides be very potential materials in harsh environments, *e.g.*, high temperature, radiation condition.

When compared to other wide bandgap semiconductors, III-nitrides exhibit an essential feature for the formation of heterostructures, such as quantum wells, quantum dots, and superlattices. The III-nitride heterostructures can be fabricated through major crystal growth techniques, including the metal-organic chemical vapor deposition (MOCVD) (Hu *et al.*, 2007c,b), hydride vapor-phase epitaxy (HVPE) (Hu *et al.*, 2010; Xu *et al.*, 2015; Ito *et al.*, 1990), and molecular beam epitaxy (MBE) (Jain *et al.*, 2000; Moustakas *et al.*, 2001; Yoshida *et al.*, 1982). However, the lattice mismatch in the heterojunctions of III-nitrides in general seriously hinders the growth of high-quality nitrides. And the shortage of lattice-matched and thermal-compatible substrate is the main difficulty for the wide development of III-nitrides (Strite and Morkoç, 1992; Moustakas *et al.*, 2001). Sapphire and silicon carbide (SiC) are the most promising substrates, and Si substrate is also in the accelerating development with low-cost and compatible epitaxial process. Since wurtzite III-nitrides are non-central-symmetric structures, they and their heterostructures exhibit the large spontaneous and piezoelectric polarization effects along the *c*-axis. Upon applying strains on the heterostructures, performances of III-nitride based devices will be significantly affected due to the large piezoelectric polarization response. That is, the piezoelectric potential (piezo-potential) is generated at the interface with the induced strain, which may act as a virtual gate to modulate the charge transport characteristics across metal-semiconductor interfaces or *p-n* junctions (also called as the piezotronic effect) (Wu and Wang, 2016; Du *et al.*, 2018a; Hu *et al.*, 2018; Pan *et al.*, 2019). Some typical GaN-based optoelectronic/electronic devices are outlined with enhanced performances under external strain. This chapter makes an outlook of fundamental properties of AlN, GaN, and InN, and provides significant insight into the potential applications of GaN-based electronic/optoelectronic devices by introducing strain effects. The key parameters of wurtzite AlN, GaN and InN are summarized in Table 1.

Aluminum Nitride

AlN possesses excellent physical properties including high melting point of $>2000^\circ\text{C}$, large thermal conductivity of $285\text{ W m}^{-1}\text{ K}^{-1}$ (Slack *et al.*, 1987), high hardness of $\sim 12\text{ GPa}$ on the plane (0001), and good capability of high-temperature and chemical resistance. AlN has a dynamically stable wurtzite phase with lattice constants ($a = 3.112\text{ \AA}$ and $c = 4.982\text{ \AA}$) (Yu, 2001), and a wide bandgap of 6.2 eV at room temperature. So, it can act as an insulating ceramic in electronic devices and exhibit the potential in optoelectronic applications at the UV spectrum. More impressively, AlN alloyed with GaN to form the ternary alloy - AlGaIn allows to extend the spectral response range from the UV to blue region, which is very suitable for optoelectronic devices (Pernot *et al.*, 2000), and is attracting the majority of interests.

Owing to the reactivity of Al with oxygen in the AlN lattice, high purity source materials and an oxygen-free environment are required to grow pure AlN. As reported, the commercial AlN typically contains extremely few oxygen (about $1 \pm 1.5\text{ at\%}$). High-quality

Table 1 Parameters of wurtzite structured AlN, GaN and InN. ("New Semiconductor Materials. Characteristics and Properties" www.ioffe.ru/SVA/NSM/Semicond/)

Parameters	AlN	GaN	InN
Bandgap (eV)	6.2	3.4	0.7
Density (g cm ⁻³)	3.255	6.15	6.81
Lattice constant (Å)	a=3.112 c=4.982	a=3.189 c=5.186	a=3.533 c=5.693
Coefficient of thermal expansion (K ⁻¹)	$\frac{\Delta a}{a}=4.15 \times 10^{-6}$ $\frac{\Delta c}{c}=5.27 \times 10^{-6}$	$\frac{\Delta a}{a}=5.59 \times 10^{-6}$ $\frac{\Delta c}{c}=3.17 \times 10^{-6}$	$\frac{\Delta a}{a}=3.8 \times 10^{-6}$ $\frac{\Delta c}{c}=2.9 \times 10^{-6}$
Thermal conductivity κ (W m ⁻¹ K ⁻¹)	285	130	45
Refraction index	2.1–2.2	2.29	2.9
Dielectric constants	$\epsilon_0=8.5 \pm 0.2$ $\epsilon_\infty=4.68\text{--}4.84$	$\epsilon_0=8.9$ $\epsilon_\infty=5.35$	$\epsilon_0=15.3$ $\epsilon_\infty=8.4$

Piezoelectric constants (C cm ⁻²)	$e_{33}=1.46$ $e_{31}=-0.60$	$e_{33}=0.73$ $e_{31}=-0.49$	$e_{33}=0.97$ $e_{31}=-0.57$
Spontaneous polarization charge P_0 (C cm ⁻²)	– 0.081	– 0.029	– 0.032

AlN is well fabricated on both silicon and sapphire substrates by employing the MBE and MOCVD growth techniques. The high-quality pure AlN crystal shows insulating electrical characteristics due to the low intrinsic carrier concentration, defect, and impurity. The undoped AlN has an electrical resistance of $10^{11} \sim 10^{13} \Omega \text{ cm}$, while the doped AlN has a decrease resistance of $10^5 \sim 10^6 \Omega \text{ cm}$. Its breakdown is found at an electrical field of $1.2\text{--}1.8 \times 10^6 \text{ V cm}^{-1}$. And the electron mobility is estimated at $300 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$. AlN also exhibits n-type and p-type conduction with refined doping growth.

The room temperature bandgap of AlN is typically characterized by the optical absorption spectra. Oxygen impurity in AlN could have an influence on the optical parameters, *e.g.*, bandgap, refraction index, and dielectric constant. The refractive index of AlN ranges from 2.1 to 2.2. The static and high-frequency dielectric constants are 8.5 and 4.6, respectively. Moreover, the phonon structure of AlN has also been investigated, and the longitudinal optical (LO), transverse optical (TO), and E₂ modes are at 910 cm^{-1} , 667 cm^{-1} and 665 cm^{-1} , respectively. (Brafman *et al.*, 1968).

Due to the piezoelectric properties, AlN is very suitable for mechanical signal sensing, mechanical energy harvesting and converting applications, such as surface acoustic wave sensors (SAWs), thin-film bulk acoustic resonator (FBAR), and micro-machined ultrasound transducers. In addition, AlN based deep UV LED (at 210 nm) (Taniyasu *et al.*, 2006) was reported for the optoelectronic applications.

Gallium Nitride

GaN has been most intensively studied in III-nitride materials, which is the typical representative of third-generation semiconductors (Strite and Morkoç, 1992; Bougrov *et al.*, 2001). GaN has a wurtzite crystal structure, and its wide bandgap of 3.4 eV allows practical applications in optoelectronic, high-power and high-frequency devices. There are three main challenges for the research on GaN: shortage of suitable substrate, large background carrier concentration, and process difficulty. Generally, undoped GaN is found to be n-type, which may be induced by nitrogen vacancies. High-quality GaN exhibits electron concentrations of $4 \times 10^{16} \text{ cm}^{-3}$ on various substrates at room temperature. Obtaining p-type GaN has permitted us to fabricate/use a large number of *p-n* junction based optoelectronic and electronic devices, *e.g.*, LEDs.

Due to the stabilities in high temperature, caustic chemicals, and ionizing radiation, GaN-based devices are of great importance used in harsh environments including high-temperature, caustic and radiation conditions. GaN is insoluble or unreactive with most solutions at room temperature, including DI water, acids, and alkali. So, conventional wet etching techniques are not very effective for GaN processing. Instead, the dry etching techniques, *e.g.*, reactive ion etching, provide the possibility for rapid etching

of GaN. The wurtzite structured GaN has lattice constants ($a = 3.189 \text{ \AA}$ and $c = 5.186 \text{ \AA}$). Additionally, the GaN lattice constant shows some variations which may be induced by growth condition, impurity concentration, and film stoichiometry.

GaN can be grown on the substrate of sapphire or SiC, despite the mismatch of lattice constants. The n-type and p-type GaN are achieved by doping with Si (or O) and Mg, respectively. However, introducing Si and Mg atoms would influence on the growth of GaN crystals, and making the thin film brittle, as a result of tensile stresses. Moreover, the coefficient of thermal expansion would be observed to be $\Delta a/a = 5.59 \times 10^{-6} \text{ K}^{-1}$ and $\Delta c/c = 3.17 \times 10^{-6} \text{ K}^{-1}$ over a temperature range of 300–700K (Maruska and Tietjen, 1969). And the thermal conductivity is $130 \text{ W m}^{-1} \text{ K}^{-1}$. The phonon modes of GaN can be identified by Raman spectrum. The $A_1(\text{TO})$ and $E_1(\text{TO})$ modes are at 533 and 559 cm^{-1} , respectively, while the E_2 modes are at 144 and 569 cm^{-1} . And the $A_1(\text{LO})$ and $E_1(\text{LO})$ modes are at 710 and 741 cm^{-1} , respectively (Strite and Morkoç, 1992). Moreover, the refraction index of GaN is 2.29 (Bougrov *et al.*, 2001), and the static and frequency dielectric constants are 8.9 and 5.35 , respectively. (Bougrov *et al.*, 2001).

GaN has excellent electrical properties for high-power, high-speed, and high-frequency electronic applications. It can withstand a large electrical breakdown field of $1.2\text{--}1.8 \times 10^6 \text{ V cm}^{-1}$. The high field electron velocity of GaN is obtained at $1.9 \times 10^7 \text{ cm s}^{-1}$. The high electron mobility of GaN is $1000 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$, and furthermore, the highest mobility is obtained in the AlGaIn/GaN heterojunctions, which is enhanced by the presence of the 2-dimensional electron gas (2°) at the heterointerface. Due to the unique properties, GaN is increasingly developing into commercialized products in blue LEDs, UV LDs, HEMTs, microwave power amplifiers, and THz devices.

Indium Nitride

InN has a small bandgap of $\sim 0.7 \text{ eV}$ at room temperature and shows very potential applications in LEDs, solar cells and high-speed electronics. InN alloyed with GaN to form the ternary alloy - GaInN LEDs, whose bandgap is tuned ranging from the IR (0.7 eV) to the UV (3.4 eV). However, there are some challenges or difficulties in InN, such as p-type doping InN, and the growth of ternary alloys with GaN or AlN with a large amount of In. Suffering from the poor thermal stability, InN cannot be grown at high-temperature conditions as the conventional AlN or GaN growth techniques. InN would fast dissolve at a temperature of $> 500^\circ\text{C}$. Similarly, InN also lacks a reasonable substrate, but it has large electron concentration ($> 10^{18} \text{ cm}^{-3}$), which is due to large densities of nitrogen vacancies. The electron mobility of InN can be as high as $3000 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ at room temperature. In addition, InN is a wurtzite crystal with lattice parameters ($a = 3.533 \text{ \AA}$ and $c = 5.693 \text{ \AA}$). Through the reflection and transmission measurements, the effective electron mass and the refraction index of InN are estimated as $m_e = 0.11m_0$ and $n = 2.9$, respectively. And the TO and LO phonon modes are at 478 and 694 cm^{-1} , respectively. (Osamura *et al.*, 1975).

Their Alloys – AlGaIn and InGaIn

Many works have focused on the properties of III-nitride alloys, because the alloys based semiconductor devices exhibit excellent characteristics with the optimization of heterostructures. Similar to GaAs alloyed with AlAs and InAs, GaN alloys with AlN and InN can be used in practical applications of high-performance solid-state optoelectronics and high-power electronics. The bandgap and lattice constant of the alloys are tuned with the composition of AlN, GaN, and InN, as shown in Fig. 1.

Fig. 1 Bandgap and lattice constant for AlN, GaN, and InN.

Fig. 2 Al compositional dependence of the $\text{Al}_x\text{Ga}_{1-x}\text{N}$ on (a) bandgap, (b) lattice constant, (c) resistivity, carrier concentration, and electron mobility at room temperature. Data from Yoshida, S., Misawa, S., Gonda, S., 1982. Properties of $\text{Al}_x\text{Ga}_{1-x}\text{N}$ films prepared by reactive molecular beam epitaxy. *Journal of Applied Physics* 53, 6844–6848.

Aluminum Gallium Nitride

AlGa_N has attracted more attention in III-nitride alloys due to the unique characteristics of AlGa_N/Ga_N heterojunctions (Strite and Morkoç, 1992; Morkoç, 2001). AlGa_N/Ga_N has a large lattice mismatch, and V-shaped cracks would form when AlGa_N was grown on Ga_N (Ito *et al.*, 1990). To date, the high-quality AlGa_N layers are commonly grown on the substrate of sapphire or (111) Si, almost always with additional Ga_N layers. As the alloy together formed with Ga_N and Al_N, $\text{Al}_x\text{Ga}_{1-x}\text{N}$ shows the tunable bandgap ranging from 3.4 eV ($x = 0$) to 6.2 eV ($x = 1$), which is essential to fabricate LEDs in the blue and deep UV regions. As measured by the Al and Ga X-ray radiation, the Al mole fraction of $\text{Al}_x\text{Ga}_{1-x}\text{N}$ can be tailored up to $x = 0.45$.

With the increasing of Al mole fraction, n-type conductivity, carrier concentration, mobility and lattice constant all show monotonous decreasing trends, as shown in Fig. 2. The resistivity has an obvious increase by ten orders of magnitude, which ranges from 10^{-4} to $10^6 \Omega \text{ cm}$, and the carrier concentration has a reduction from 2×10^{20} to 10^{17} cm^{-3} , when the Al mole fraction increases from $x = 0$ to $x = 0.4$. In addition, $\text{Al}_x\text{Ga}_{1-x}\text{N}$ has a good thermal stability up to 900°C , when $x = 0.5$. The refraction index (400–500 nm) is ~ 2.42 as $x = 0.2$. Moreover, the increase of the phonon frequencies with the Al mole fraction is smaller than expected from a linear extrapolation for the TO and E_2 modes while it is slightly larger for the $E_1(\text{LO})$ mode. Together with Ga_N, AlGa_N has been developed into commercial products in the blue and UV LEDs, blue LDs, UV detectors, and HEMTs.

Indium Gallium Nitride

Also as a tunable bandgap alloy, InGa_N has a direct bandgap span from the infrared (0.7 eV for In_N) to the ultraviolet (3.4 eV for Ga_N). By changing the amount of In, the properties of $\text{In}_x\text{Ga}_{1-x}\text{N}$ can be obviously tuned, as shown in Fig. 3. The ratio of In/Ga is in general between 0.02/0.98 and 0.3/0.7. The lattice constant and bandgap of $\text{In}_x\text{Ga}_{1-x}\text{N}$ show linear relations with the In mole fraction (Nagatomo *et al.*, 1989; Osamura *et al.*, 1972). The In is active at high temperature, and may occur the re-evaporation of In during the growth. As reported, a phase separation is found in the $\text{In}_x\text{Ga}_{1-x}\text{N}$ alloy with low In mole fraction

Fig. 3 InN compositional dependence of the $\text{In}_x\text{Ga}_{1-x}\text{N}$ on bandgap at room temperature. Data from Osamura, K., Nakajima, K., Murakami, Y., *et al.*, 1972. Fundamental absorption edge in GaN, InN and their alloys. Solid State Communications 11, 617–621.

through a high-temperature annealing processing (700°C, Ar) (Osamura *et al.*, 1975). The high-quality single crystal $\text{In}_{0.22}\text{Ga}_{0.78}\text{N}$ can be achieved at the high-temperature (800°C) CVD growth (Yoshimoto *et al.*, 1991).

Devices and Applications

Due to the unique characteristics (*e.g.*, tunable direct bandgap, high electron mobility, high saturation velocity, high absorption coefficient, and high thermal stability and conductivity), AlN, GaN, InN and their alloys have paved the way into the high-performance optoelectronic and electronic devices, and the related commercial applications. Specifically, InGaN/GaN-based LEDs and AlGaN/GaN-based HEMTs are two key devices widely studied for the research and applications of III-nitrides. Furthermore, III-nitrides (*e.g.*, GaN) exhibit spontaneous and piezoelectric polarization due to the non-central-symmetric wurtzite structure. The strong polarity of the covalent bond between Ga and N atoms causes the spontaneous polarization. The separation of the dipole centers in the GaN crystal induces large piezoelectric polarization upon strain along the *c*-axis. Different from the Si and GaAs semiconductors, polarization is a vital effect on the III-nitrides, which greatly affects device performances. Indeed, it is of great importance to investigate the polarization effect on the III-nitride devices. Additionally, piezoelectric polarization potential (piezo-potential) induced by external strain can effectively control carrier transport characteristics at the interface, which is also called piezotronic effect (Pan *et al.*, 2019; Hu *et al.*, 2018).

Piezotronic Effect

The wurtzite structured AlN, GaN and InN semiconductors both possess piezoelectric and semiconductor properties, and have large piezoelectric constants (see Table 1). Upon an external strain, the piezo-potential is produced at the heterointerface along the *c*-axis, and has an influence on the carrier transport characteristics, which is the basis of the piezotronic effect (Wu and Wang, 2016; Du *et al.*, 2018a; Hu *et al.*, 2018; Pan *et al.*, 2019).

Polarization is related to the polarity of the crystal. Under a normal compressive stress, the *c*-plane GaN nanowire exhibits the tunable Schottky barrier behavior with the piezoelectric polarization, but the *m*-plane GaN nanowire does not show that (Zhao *et al.*, 2015). The piezoelectric polarization intensity is dependent on the strain of the crystal. When there is no strain but spontaneous polarization in the III-nitride heterojunction, the spontaneous polarization is along the [0001] direction, the negative polarization charge will be distributed on the Ga-plane, and the positive polarization charge will be distributed on the N-plane. When it is subjected to the biaxial tensile stress, the piezoelectric polarization along the *c*-axis is aligned with the spontaneous polarization; when it is subjected to the biaxial compressive stress, the piezoelectric polarization along the *c*-axis is opposite to the spontaneous polarization. The displaced charge centers of the Ga cations and N anions under strain cause the generation of the electric dipole moment in the crystal, and thus piezo-potential is formed in the macroscopic straining orientation. The piezo-potential intensity of the III-nitride heterojunctions can reach the order of 1 MV cm^{-1} , and the polarization charge density can reach $1 \times 10^{12} \text{ cm}^{-2}$, which can significantly tune the band structure of the heterojunction, thus affecting the carriers transport behavior.

Upon strains on the crystal, spontaneous and piezoelectric polarizations are simultaneously demonstrated. Net polarization (P_{NP}) in crystal volume unit is the sum of spontaneous (P_{SP}) and piezoelectric polarization (P_{PE}):

$$P_{NP} = P_{SP} + P_{PE}$$

For a given material, the piezoelectric property can be evaluated through the polarization vector P and the strain tensor S_{jk} :

$$P_i = e_{ijk} S_{jk}$$

where e_{ijk} is a third-rank tensor of piezoelectric coefficients.

The relationship between electricity and elasticity through the piezoelectric effect can be given as:

$$\sigma = c_E S - e^T E$$

$$D = e S + \kappa E$$

where D is the electric polarization, σ is the stress tensor, c_E is the elastic tensor, and κ is the dielectric tensor.

For an III-nitride layer on a biaxial strain, the effective piezoelectric polarization is:

$$P_z^{\text{piezo}} = [e_{31} - (C_{31}/C_{31}) \cdot e_{33}] \cdot \varepsilon_{\perp}$$

where C_{31} and C_{33} are elastic constants, and $\varepsilon_{\perp}$ is the in-plane strain. For coherently strained $\text{Al}_x\text{Ga}_{1-x}\text{N}$ on a relaxed GaN layer, the strain ε is expected to be proportional to x . It is tensile and given by

$$\varepsilon_{\perp} = 2x(a_{\text{GaN}} - a_{\text{AlGa}})/a_{\text{AlGa}}$$

The magnitude of the strain reduces to 0.0495x for the case of the c -plane lattice constants of 3.112 Å and 3.189 Å for AlN and GaN, respectively. Here x is in the range of 0–1 and indicates the AlN mole fraction in the alloy. The piezoelectric polarization is $P_z^{\text{piezo}} = -4.26x \times 10^{-2} \text{ C cm}^{-2}$ or $2.66x \times 10^{13} \text{ e cm}^{-2}$ and points along the [000-1] direction. The corresponding difference in spontaneous polarization between $\text{Al}_x\text{Ga}_{1-x}\text{N}$ and GaN is also expected to be proportional to x and is given by $\Delta P^{\text{piezo}} = -4.26x \times 10^{-2} \text{ C cm}^{-2}$ or $3.25x \times 10^{13} \text{ e cm}^{-2}$. The two polarization effects have the same sign for Ga-polarity and tensile strain in the alloy, and point in the [000-1] direction (Morkoç *et al.*, 1999). In the layer of $\text{In}_x\text{Ga}_{1-x}\text{N}$, the differential spontaneous polarization between $\text{In}_x\text{Ga}_{1-x}\text{N}$ and GaN is much smaller, $\Delta P^{\text{pon}} = -0.003x$, corresponding to $1.88x \times 10^{12} \text{ e cm}^{-2}$. Furthermore, the $\text{In}_x\text{Ga}_{1-x}\text{N}$ layer on GaN would be under compressive strain. The amplitude of the in-plane strain is $\varepsilon_{\perp} = -0.195x$ if 3.533 Å and 3.189 Å are used for c -plane lattice constants for InN and GaN. Here x is in the range of 0–1 and indicates the InN mole fraction, and $\Delta P^{\text{piezo}} = +0.176x$ or $1.1x \times 10^{14} \text{ e cm}^{-2}$. For an InN mole fraction of 0.15, $P_z^{\text{piezo}} = 1.65 \times 10^{13} \text{ e cm}^{-2}$. In this case, the piezoelectric polarization dominates and is opposite in direction but even larger in absolute magnitude (Morkoç, 2001; Morkoç *et al.*, 1999). For the AlGa case, the sign of piezoelectric polarization is such as to produce a potential energy for electrons sloping down from the Ga-plane to the N-plane. In a structure with Ga polarity, the potential will slope down from the AlGa surface toward the AlGa/GaN heterointerface. This potential gradient will help to drive free electrons to the heterointerface forming a 2°. In the presence of an ohmic metal contact on the AlGa surface, electrons will flow from the contact toward the 2° below that layer (Morkoç, 2001; Morkoç *et al.*, 1999).

AlGa/GaN HEMTs

Due to the excellent performances in high-power, high-speed and high-frequency, AlGa/GaN HEMTs have great application prospects, such as radio-frequency, power amplifiers, broadband communication, radar, power inverter, and sensors. Fig. 4(a) shows the schematic illustration of the AlGa/GaN HEMT.

GaN has many advantages including higher breakdown voltages and higher operational temperature. Large lattice mismatch between AlN and GaN induces a strain in the AlGa layer, producing a piezoelectric field. Together with the large conduction band offset and the spontaneous polarization result in high electron sheet charge density.

Various device optimization techniques are developed: (1) the use of the field-plate, T-shaped or Y-shaped gate electrodes; (2) the insertion of AlN barrier between the GaN and AlGa layers that increases the conduction band offset and the 2DEG density and decreases the alloy disorder scattering, leading to the increase of mobility; and (3) the introduction of the double-heterojunction structure that enhances the 2DEG transport properties, *e.g.*, the InGa layer under the channel brings negative polarization charges at the heterointerface, result in improving the carrier confinement in the channel. In general, AlGa/GaN HEMTs exhibit the depletion-mode (D-mode) behavior. However, the enhancement-mode (E-mode) is getting progress. Several approaches are presented for the E-mode technology by the usages of very thin AlGa layers, fluoride-based plasma treatment, the recess gate structure, and the InGa cap layers.

Another way to optimize the device performance is by adopting the piezotronic effect to control the carrier transport in the AlGa/GaN HEMT. The existence of 2DEG at the AlGa/GaN heterointerface is the basic to control carriers transport behavior for achieving special performances, which is related to the spontaneous and piezoelectric polarization of the strained AlGa and GaN layers. Without an external strain, positive/negative polarization charges turn up at the bottom/top surface of the AlGa layer due to intrinsic polarization. Electrons are driven by the electric fields to the triangle-shaped potential well at the AlGa/GaN heterointerface, forming the 2DEG. Under a tensile strain, piezoelectric charges are newly generated at the top surface of the GaN layer, causing that the potential well and the net positive polarization charges become shallower and decrease at the AlGa/GaN heterointerface, as shown in Fig. 4(b) and (c). Thus, fewer electrons are confined in the potential well and current becomes smaller with the increase of tensile strain. Similarly, the compressive strain is also investigated in HEMT, demonstrating that it will increase the current due to more electrons in the potential well. Moreover, the heterojunction electron gas and electric transport properties

Fig. 4 Piezotronic effect on the AlGaIn/GaN HEMTs. (a) A typical schematic of HEMT. (b) Output ($I_{ds} - V_{ds}$) characteristics of the strained HEMT (the dashed and solid lines represent the strain-free and tensile strain conditions, respectively). (c) Schematic energy band diagrams of the AlGaIn/GaN heterojunction under tensile strain condition. (d) The performance of the AlGaIn/AlN/GaN heterostructure microwires under strain at various temperature. Reproduced with permissions from Liu, T., Jiang, C., Huang, X., *et al.*, 2017. Electrical transportation and piezotronic-effect modulation in AlGaIn/GaN MOS HEMTs and unpassivated HEMTs. *Nano Energy* 39, 53–59. Wang, X., Yu, R., Jiang, C., *et al.*, 2016. Piezotronic effect modulated heterojunction electron gas in AlGaIn/AlN/GaN heterostructure microwire. *Advanced Materials* 28, 7234–7242.

of AlGaIn/AlN/GaN microwires at low temperatures are easily tuned by piezotronic effect, as shown in Fig. 4(d). The conductance shows more remarkable change at low temperature under strains, due to the suppressed screening against piezoelectric polarization. Therefore, piezotronic effect is an innovative way to optimize the performance of HEMT and will provide some inspiration for designing novel human-machine interfaces (Zhang *et al.*, 2020).

InGaIn/GaN LEDs

Due to the high brightness, tunable/wide emission wavelength, and high reliability, III-nitride LEDs (*e.g.*, InGaIn/GaN MQW) are being extensively developed into energy-efficient solid-state light sources aim to replace the incandescent and gas discharge lamps (Iso *et al.*, 2007; Nakamura *et al.*, 1993). The white-light LEDs is essential to achieving $> 200 \text{ lm W}^{-1}$ in market-ready systems by 2025 (Morgan Pattison *et al.*, 2018). The high-performance LEDs demonstrate some ubiquitous applications in the field of white light illumination, full-color displays, visible light communication (VLC), and medical micro-imaging vehicles. Moreover, the newly developed LEDs with micro-pixelated design (*i.e.*, micro-LEDs) enables monolithic integration of multiple devices, and is an ideal platform for single-chip full-color emissive microdisplays, promising to challenge the conventional LEDs and OLED technologies.

Together with the piezoelectric polarization, the optical excitation of the wurtzite structured III-nitride semiconductors can be tuned with the use of strain, leading to the piezo-phototronic effect (Wu and Wang, 2016; Du *et al.*, 2018a; Pan *et al.*, 2019). It is an emerging field of band structure engineering through interfacing tuning with the coupling of semiconductor properties, piezoelectric polarization, and optical excitation. Under the strain-induced piezoelectric polarization charges (piezo-charges) as a virtual “gate”, the band structure can be effectively modulated to achieve tunable optoelectronic performances, including light emission enhancement (Yang *et al.*, 2011), solar cell efficiency (Sun *et al.*, 2019), dual-channel VLC (Du *et al.*, 2016), and pressure sensing/imaging (Pan *et al.*, 2013).

Ongoing research is dedicated to improving device performances, *e.g.*, the structure for more efficient light generation/extracting. In addition, the piezo-phototronic effect is also used to enhance the performances of InGaIn/GaN LEDs. Thermal issue is inevitable for LEDs that takes near 80% of the input power and thus causes temperature increase, leading to the degradations in lifetime and light-output, or risking catastrophic failure (Du *et al.*, 2018b; Christensen and Graham, 2009; Hu *et al.*, 2007a). Additionally, the integrated EL intensity at 364K is only 67.8% of that at 300K (Du *et al.*, 2018b). And hence, it is very important to deal with thermal issues in high power LEDs. Impressively, an effective way to relieve the thermal issue is the use of the piezo-phototronic effect, which can enhance the EL intensity at the high temperature with strains. The micro-stripe arrayed blue InGaIn/GaN MQW LED is shown in Fig. 5(a). Due to the lattice mismatch of the InGaIn/GaN heterointerface, in-plane compressive strain in the InGaIn layers causes the energy band tilted and gradually misaligns the wave functions of electron and hole. Upon an external strain, piezo-potential is generated and opposite to that induced by internal strain, partly counteracting the piezoelectric charges in the vicinity of the interface, which makes the energy band more flatten and the wave functions of electron and hole more overlapped. Consequently, the electron/hole recombination rate increases, and so does the emission efficiency of micro-LED. The EL intensity increases with the increase of external strain (Fig. 5(b)). When the temperature increases from 300K to 380K with no external strain, the EL intensity gets a continuous decrease, probably due to the increase of nonradiative recombination

Tuning carrier lifetime in InGaN/GaN LEDs via strain compensation for high-speed visible light communication. *Scientific Reports* 6, 37132.

behavior including defects, Auger recombination and dislocations, and the decrease of the spontaneous emission rate as well. A 4.6 nm red-shift is also observed in emission wavelength, induced by the shrinkage of the energy band (Fig. 5(c)). These worse conditions caused by the thermal issue do harm to the lighting. Obviously, the integrated EL intensity is monotonously enhanced when the external strain increases with temperatures (Fig. 5(d)) (Du *et al.*, 2018b). In addition, the piezo-phototronic effect has potential applications in high-speed optoelectronic devices, such as ultra-fast display or VLC. With the strain modulation, the green InGaN/GaN SQW LED exhibits an increase of the PL intensity and a 55% reduction of the carrier lifetime with strains (Fig. 5(e) and (f)), which dramatically increase the single-chip VLC modulation width to 117 MHz (Du *et al.*, 2016).

Conclusion and Outlook

AlN, GaN, InN and their alloys exhibit outstanding structural, electrical and optical properties, *e.g.*, high electron mobility, high saturation velocity, direct and tunable bandgap, large dielectric breakdown field, high absorption coefficient, and high thermal stability and conductivity, which are very promising semiconductors for industrial applications of optoelectronics and electronics in harsh environments. The III-nitrides have thermodynamically stable wurtzite crystal phase at ambient conditions, and the direct bandgap ranges from 6.2 eV of AlN, 3.4 eV of GaN, to 0.7 eV of InN. Their ternary alloys such as AlGaIn and InGaIn provide the possibility of tuning the bandgaps continuously span from the deep UV into the whole visible spectrum.

Lack of lattice-matched substrates, insufficient control of impurity levels, defects and dislocations, difficult growth of high-quality p-type doping layers, and process difficulty for layer pattern are still challenges for the ongoing research and development on the III-nitrides. Sapphire, SiC and Si are presented to be suitable substrates for III-nitrides growth. High-quality AlN, GaN, InN and their alloys can be grown by the use of the MBE and MOCVD techniques. But it is still needed to develop the high-quality III-nitride layers and heterostructures for future high-power, high-performance electronic and optoelectronic applications.

Due to the non-central-symmetric wurtzite structures, III-nitrides simultaneously demonstrate spontaneous and piezoelectric polarization. The electrical or optical properties of III-nitrides can be effectively tuned/controlled by external strains, which lead to the large piezoelectric polarization response. And hence, the piezotronic (or piezo-phototronic) effect is employed, by strain-induced piezoelectric charges at the heterointerface, to modulate the charge generation, combination, and transport characteristics. The typical devices, *i.e.*, AlGaIn/GaN HEMTs and InGaIn/GaN QW LEDs are demonstrated, and show the enhanced performances under the effect of external strains, which represents an effective approach for device optimization.

This chapter makes an outlook of fundamental properties of AlN, GaN, and InN, and provides significant insight into the potential applications of GaN-based electronic/optoelectronic devices by introducing strain effects. However, a large amount of

work should be done for further investigations on approaching the level of understanding of technologically important materials as the first-/second-generation semiconductors (e.g., Si and GaAs).

This is an update of Hintzen, H.T., Li, Y.Q., 2004. Novel nitride phosphors. In: The Encyclopedia of Materials: Science and Technology, second ed. Elsevier Ltd. doi:10.1016/B0-08-043152-6/01910-0.

Ce- and Tb-Doped Rare-Earth Silicon Oxynitrides

Long-wavelength $\text{Ce}^{3+} 5d \rightarrow 4f$ band emission was observed in Y–Si–O–N materials (van Krevel *et al.*, 1998); its exact position depends on the nephelauxetic effect, crystal field splitting of the $5d$ -level and Stokes shift. The crystal field splitting decreases when more N^{3-} versus O^{2-} is coordinated to Ce^{3+} , which is ascribed to the higher formal charge of nitrogen versus oxygen (van Krevel *et al.*, 1998). The Stokes shift becomes smaller in the series $\text{Y}_5(\text{SiO}_4)_3\text{N} > \text{Y}_4\text{Si}_2\text{O}_7\text{N}_2 > \text{YSiO}_2\text{N} > \text{Y}_2\text{Si}_3\text{O}_3\text{N}_4$, related to an increasing rigidity due to more extended cross-linking between SiX_4 ($\text{X} = \text{O}, \text{N}$) tetrahedra in this direction (respectively: single SiX_4 units, Si_2X_7 dimers, Si_3X_9 rings, and $(\text{Si}_3\text{X}_7)_n$ layers).

The highest emission wavelength was observed for $\text{Y}_2\text{Si}_3\text{O}_3\text{N}_4\text{:Ce}$ (≈ 504 nm), whose position can only be negligibly influenced by replacement of $(\text{SiN})^+$ by $(\text{AlO})^+$ resulting in $\text{Y}_2\text{Si}_{3-x}\text{Al}_x\text{O}_{3-x}\text{N}_{4-x}\text{:Ce}$ compounds (van Krevel *et al.*, 2000). Despite a high solid solubility up to $x = 0.6$ which significantly modifies the chemical composition of the host lattice, evidently the local coordination around the Ce^{3+} ion remains almost the same. This effect was ascribed to the larger ionic size of Ce^{3+} as compared to Y^{3+} resulting in preferential coordination of the dopant ion with oxygen as compared to nitrogen (van Krevel *et al.*, 2000).

Other examples of Ce^{3+} -doped rare-earth silicon oxynitride phosphors are $\text{La}_5\text{Si}_3\text{O}_{12}\text{N}$, $\text{La}_4\text{SiO}_7\text{N}_2$, LaSiO_2N , and $\text{La}_3\text{Si}_8\text{O}_4\text{N}_{11}$ (Dierre *et al.*, 2007). All these materials emit blue light upon UV excitation; the strongest emission was observed for the $\text{La}_3\text{Si}_8\text{O}_4\text{N}_{11}$ host, which showed also the highest doping level (20 at%) at which concentration quenching occurred.

In a similar way the position of the $5d$ excitation band of Tb^{3+} incorporated in these host lattices can be shifted (van Krevel, 2000). For $\text{Y}_4\text{Si}_2\text{O}_7\text{N}_2\text{:}10\%\text{Tb}$ the excitation maximum at 255–265 nm is overlapping with the absorption edge of the host lattice, resulting in both a high absorption (90%) and quantum efficiency (85%) for 254 nm excitation (van Krevel, 2000). In this way the necessity of sensitization of the Tb emission in commercial phosphors by co-doping with Ce (Blasse and Grabmaier, 1994) can be avoided.

Rare-Earth-Doped Sialon Materials

α -Sialon (for α -Si–AlON) materials originate from α - Si_3N_4 in which Si has been replaced by Al, N has been replaced by O, and for charge compensation a metal M is added, resulting in the general composition $\text{M}_{m/\text{val}}\text{Si}_{12-(m+n)}\text{Al}_{(m+n)}\text{O}_n\text{N}_{16-n}$ ($\text{M} = \text{Li}, \text{Ca}, \text{rare earth}$). These materials are well known because of their high durability under chemical, thermal, and mechanical attack. Based on the criterion of bond directness, these matrices are considered to be promising for rare-earth activation (Grekov and Chernovets, 1998).

Doping the α -Sialon matrix with Tb^{3+} gives the characteristic green $^5\text{D}_4 \rightarrow ^7\text{F}_5$ emission ~ 545 nm (Xie *et al.*, 2002; van Krevel *et al.*, 2002), but with low quantum efficiency for 254 nm excitation (van Krevel *et al.*, 2002). This is probably due to overlap of the $5d$ Tb^{3+} excitation band with the α -Sialon host-lattice conduction band resulting in radiationless transitions by photo-ionization processes (van Krevel *et al.*, 2002).

Pr^{3+} -doped α -Sialon shows red luminescence due to $4f \rightarrow 4f$ transitions from the $^3\text{P}_0$ and $^1\text{D}_2$ emitting levels (Xie *et al.*, 2002). The emission band of Ce^{3+} in the α -Sialon matrix is at quite a high wavelength (≈ 495 nm) (Grekov *et al.*, 1999), 515–540 nm (van Krevel *et al.*, 2002). The exact position of the $5d \rightarrow 4f$ emission band depends on the excitation wavelength, indicating that some variation exists in local Ce coordination (van Krevel *et al.*, 2002).

For Eu^{2+} doping a similar $5d \rightarrow 4f$ band emission was observed in the range 550–590 nm (Xie *et al.*, 2002; van Krevel *et al.*, 2002). The emission peak shifts to a longer wavelength with increasing amounts of europium (Xie *et al.*, 2002). Despite systematic changes in chemical composition of the host lattice (i.e., m and n), the emission is not strongly influenced. This indicates that the Eu^{2+} ion dominates its local coordination, induced by the difference in size and the available space in the interstitial site (van Krevel *et al.*, 2002). The Eu-doped α -Sialon samples are yellow-green colored (Xie *et al.*, 2002; van Krevel *et al.*, 2002), and therefore can be efficiently excited by visible radiation in the range 400–450 nm.

Recently, long wavelength band emission was also reported for rare-earth ions in Sialon glasses (up to 500 nm for Ce^{3+} (de Graaf *et al.*, 2003a), and as long as 640 nm for Eu^{2+} (de Graaf *et al.*, 2003b)).

Pr^{3+} -doped β -Sialon of composition $\text{Si}_{6-z}\text{Al}_z\text{O}_z\text{N}_{8-z}\text{:Pr}_x$ ($z = 0\text{--}2.0$, $x = 0.016$) showed red luminescence in the range 600–650 nm upon excitation with 460 nm blue light, indicating that the phosphor can be excited by blue LEDs (Liu *et al.*, 2011). The luminescence spectra showed that the integrated red emission from 600 to 650 nm increased with temperature between 298 and 473 K. This unexpected phenomenon is proposed to be the result of the coupling of the $^1\text{D}_2$ and $^3\text{P}_0$ excited states of the $4f^2$ configuration.

The luminescence of Eu^{2+} in two oxonitridoaluminosilicates (Sialons), namely $\text{SrSi}_5\text{AlO}_2\text{N}_7$ and $\text{SrSiAl}_2\text{O}_3\text{N}_2$, was investigated (Xie *et al.*, 2005). The samples were synthesized by high temperature sintering under N_2 atmosphere. A single broad band in the blue-green region was observed upon UV excitation for both $\text{SrSi}_5\text{AlO}_2\text{N}_7\text{:Eu}^{2+}$ and $\text{SrSiAl}_2\text{O}_3\text{N}_2\text{:Eu}^{2+}$ at room temperature.

Fig. 1 Normalized emission spectra for $\text{Sr}_{0.98-x}\text{Ba}_x\text{Si}_2\text{O}_2\text{N}_2:2\%\text{Eu}$ ($x = 0 - 0.98$) at RT ($\lambda_{\text{ex}} = 450$ nm). Reprinted with permission from Bachmann, V., Ronda, C., Oeckler, O., Schnick, W., Meijerink, A., 2009. Color point tuning for $(\text{Sr,Ca,Ba})\text{Si}_2\text{O}_2\text{N}_2:\text{Eu}^{2+}$ for white light LEDs. Chemistry of Materials 21, 316–325, Copyright 2009, American Chemical Society.

The short-wavelength emission were attributed to the weak crystal-field strength as a result of long distances between the dopant ion and the ligand anions. The effect of the Eu^{2+} concentration on the emission intensity was discussed and the CIE chromaticity coordinates of both samples were presented.

An important step forward on a related composition was made recently through a cooperation between the University of Innsbruck and OSRAM GmbH (Hoerder *et al.*, 2019). The phosphor $\text{Sr}[\text{Li}_2\text{Al}_2\text{O}_2\text{N}_2]:\text{Eu}^{2+}$ was developed, which is an almost ideal material for pcLEDs, in terms of optimal spectral position for a red phosphor, exceptionally small spectral full width at half maximum and excellent thermal stability.

Eu-Doped Alkaline-Earth Silicon Nitrides and Oxynitrides

Deep-red band emission was discovered by van Krevel (2000) for Eu^{2+} incorporated in alkaline-earth silicon nitrides, such as $\text{M}_2\text{Si}_5\text{N}_8:\text{Eu}$ ($\text{M} = \text{Ca}, \text{Sr}, \text{Ba}$; $\lambda_{\text{em}} = 620\text{--}640$ nm) and $\text{BaSi}_7\text{N}_{10}:\text{Eu}$ ($\lambda_{\text{em}} \approx 660$ nm). Emission above 600 nm is very uncommon for Eu^{2+} (Blasse and Grabmaier, 1994), and this is a consequence of the large nephelauxetic effect and large crystal field splitting caused by nitrogen. Due to a concomitant shift of the $4f \rightarrow 5d$ absorption band into the visible region, these compounds are strongly orange-red colored. Moreover, these materials are capable of efficiently converting the absorbed 400–450 nm radiation into red light. Because of the high application potential for light emitting diode (LED) lighting when combined with UV-blue emitting LEDs, in 1999 a patent was filed on such materials (Hintzen *et al.*, 2001). In the meantime, also the thermoluminescence behavior of $\text{Ba}_2\text{Si}_5\text{N}_8:\text{Eu}$ was reported by Höpfe *et al.* (2000).

For Eu doped in host lattices with a higher M/Si ratio (i.e., lower degree of cross-linking between SiN_4 tetrahedra), the emission is at lower wavelengths, i.e., blue-green emission at ~ 515 nm for $\text{MgSiN}_2:\text{Eu}$ (Gaido *et al.*, 1974) and red emission at ~ 620 nm for $\text{CaSiN}_2:\text{Eu}$ (Lee *et al.*, 1997). For MgSiN_2 also the luminescence of the rare-earth ions Sm and Yb was studied (Dubrovskii *et al.*, 1981). While generally excitation takes place with electromagnetic radiation, for $\text{MgSiN}_2:\text{Eu}$ also data have been published for cathode-ray excitation (Bondar *et al.*, 2001) and for $\text{CaSiN}_2:\text{Eu}$ also electroluminescence was reported (Lee *et al.*, 1997).

Large amount of oxygen results in silicon-oxynitrides, in which deep red Eu^{2+} emission at 650 nm was reported for $\text{LaEu-Si}_2\text{N}_3\text{O}_2$, while green band emission at 549 nm was found for $\text{La}_{0.9}\text{Eu}_{0.1}\text{Si}_3\text{N}_{5-x}\text{O}_x$ (Uheda *et al.*, 2000). The amount of oxygen can be further increased by replacement of $(\text{SiN})^+ \rightarrow (\text{AlO})^+$ and/or $(\text{LaN})^\circ \rightarrow (\text{MO})^\circ$ ($\text{M} = \text{alkaline earth}$), resulting in, for example, $\text{SrSiAl}_2\text{O}_3\text{N}_2$ for which blue-green Eu^{2+} emission and blue Ce^{3+} emission were reported at about 487 nm and 466 nm, respectively (Fiedler *et al.*, 2002).

The color tuning of the efficient LED phosphor $\text{Sr}_{1-x-y-z}\text{Ca}_x\text{Ba}_y\text{Si}_2\text{O}_2\text{N}_2:\text{Eu}_z^{2+}$ ($0 \leq x, y \leq 1$; $0.005 \leq z \leq 0.16$) was investigated (Bachmann *et al.*, 2009). Tuning of the emission color was achieved by changing the Eu^{2+} concentration or by substitution of the host lattice cation Sr^{2+} by Ca^{2+} or Ba^{2+} (Fig. 1). Luminescence data show that the quenching temperature decreases with substitution of Sr by Ca, whilst for Ba substitution the quenching temperature remains high. Color tuning by partial substitution of Sr^{2+} by Ba^{2+} is the best way to optimize the color point of the phosphor while retaining high quantum yield and high quenching temperature.

The $\text{Sr}_2\text{Si}_5\text{N}_8:\text{Eu}^{2+}$ nitride phosphor was prepared by the carbothermal reduction and nitridation method and characterized by X-ray diffraction (Piao *et al.*, 2006). Two absorption bands were observed with maxima at about 330 and 420 nm, so that the phosphor can be effectively excited by InGaN LEDs. The emission peak position of $(\text{Sr}_{1-x}\text{Eu}_x)_2\text{Si}_5\text{N}_8$ materials was observed to shift

from 618 to 690 nm with increasing dopant ion concentration. The redshift behavior of the emission band was discussed making reference to the configuration coordinate model. Related results were simultaneously obtained in a separate study on the broader system of Eu^{2+} -doped $\text{M}_2\text{Si}_5\text{N}_8$ ($\text{M} = \text{Ca}, \text{Sr}, \text{Ba}$) (Li *et al.*, 2006). The materials with $\text{M} = \text{Ca}, \text{Sr}$ showed typical broad band emission in the orange to red spectral range, depending on M and the Eu^{2+} concentration. $\text{Ba}_2\text{Si}_5\text{N}_8:\text{Eu}^{2+}$ showed emission maxima shifting from 580 to 680 nm with increasing Eu^{2+} content. The long-wavelength excitation and emission was attributed to the effect of covalency and a strong crystal-field on the $5d \rightarrow 4f$ band of Eu^{2+} in the nitride coordination sphere. The conversion efficiency increases moving from Ca to Ba and Sr upon excitation at 465 nm. In particular, $\text{Sr}_2\text{Si}_5\text{N}_8:\text{Eu}^{2+}$, with a high quantum efficiency (75%–80%) and a minimal thermal quenching at 150°C, was found to be a valuable red-emitting phosphor for white-LED applications. The influence of the replacement of Sr by Ca on the structural and luminescence properties of Eu^{2+} -doped $\text{Sr}_2\text{Si}_5\text{N}_8$ was studied in detail from the crystallographic and spectroscopic point of view (Li *et al.*, 2008). The maximum of the emission band of the dopant can be shifted by partial introduction of Ca in $\text{Sr}_2\text{Si}_5\text{N}_8:\text{Eu}^{2+}$, resulting in red emission moving from 620 to 643 nm.

The orange-red emitting phosphors based on $\text{M}_2\text{Si}_5\text{N}_8:\text{Eu}^{2+}$ ($\text{M} = \text{Sr}, \text{Ba}$) have shown to have the potential to be widely utilized in white LEDs due to their enhancement of the color rendering index, giving rise to warm white light emission. For this reason, the thermal degradation in air was investigated for a series of $\text{M}_{2-x}\text{Si}_5\text{N}_8:\text{Eu}_x$ ($\text{M} = \text{Sr}, \text{Ba}$) phosphors prepared by solid-state reaction. (Yeh *et al.*, 2012). Degradation was only observed in $\text{Sr}_{2-x}\text{Si}_5\text{N}_8:\text{Eu}_x$ with $x = 0.10$, but it did not occur in $\text{Sr}_{2-x}\text{Si}_5\text{N}_8:\text{Eu}_x$ with $x = 0.02$ and the Ba analog with $x = 0.10$. The thermal degradation in $\text{Sr}_{2-x}\text{Si}_5\text{N}_8:\text{Eu}_x$ with $x = 0.10$ is attributed to the formation of an amorphous layer on the surface of the phosphor grains during the heat treatment in oxidizing atmosphere, accompanied by the oxidation of Eu^{2+} ions to Eu^{3+} .

The Eu^{2+} -doped phosphors $\text{Ca}_{1-x}\text{Eu}_x\text{AlSiN}_3$ ($x = 0\text{--}0.2$) were prepared by self-propagating high-temperature synthesis (Piao *et al.*, 2007). A strong absorption band at 460 nm was observed in the excitation spectra, which is suitable for the blue light emitted by InGaN/GaN LEDs. The optimized sample $\text{Ca}_{0.98}\text{Eu}_{0.02}\text{AlSiN}_3$ gave rise to red emission peaking at 649 nm. The CIE coordinates (0.647, 0.347) with high color saturation indicated that this is a promising candidate as a red emitting phosphor for InGaN/GaN-based white LEDs for general illumination or displays.

The new phosphor $\text{SrAlSi}_4\text{N}_7:\text{Eu}^{2+}$ was synthesized at high temperature in a radio-frequency furnace (Hecht *et al.*, 2009). The crystal structure of the host compound $\text{SrAlSi}_4\text{N}_7$ was determined using X-ray diffraction data. The Eu^{2+} -doped compound shows a typical broadband emission in the orange-red spectral region ($\lambda_{\text{max}} \approx 632$ nm for 2% Eu doping level, 450 nm excitation). The luminescence behavior makes the phosphor an attractive candidate material as red component in warm white light LEDs with high color rendering index.

The compounds $\text{M}[\text{Mg}_3\text{SiN}_4]$ ($\text{M} = \text{Ca}, \text{Sr}, \text{Eu}$) were prepared by solid-state reaction (Schmiechen *et al.*, 2014). They are isotypic and crystallize in the tetragonal space group $I4_1/a$, as shown by single-crystal X-ray diffraction. $\text{Sr}[\text{Mg}_3\text{SiN}_4]:\text{Eu}^{2+}$ is characterized by red luminescence ($\lambda_{\text{max}} = 615$ nm) with one of the narrowest red emission reported in the literature so far for Eu^{2+} -phosphors (~ 43 nm). On the basis of this outstanding narrow red emission, $\text{Sr}[\text{Mg}_3\text{SiN}_4]:\text{Eu}^{2+}$ may point the way to a next generation of red phosphor materials for application in illumination-grade white pc-LEDs.

Eu-Doped Aluminum-Oxynitrides With β -Alumina and Other Structures

The previously mentioned replacement $(\text{SiN})^+ \rightarrow (\text{AlO})^+$ can be used in the reversed direction for the design of oxynitrides starting from aluminates. Another way to obtain oxynitrides from M-aluminates is to replace (M^{n+}O) by $(\text{M}^{(n+1)+}\text{N})$. Examples are given by $\text{LaAl}_{12}\text{O}_{18}\text{N}$ with the magnetoplumbite structure (Wang *et al.*, 1988) (derived from $\text{SrAl}_{12}\text{O}_{19}$ by replacement of $(\text{SrO})^\circ$ by $(\text{LaN})^\circ$) and $\text{BaAl}_{11}\text{O}_{16}\text{N}$ with the β -alumina structure (Jansen *et al.*, 1997) (derived from $\text{NaAl}_{11}\text{O}_{17}$ by replacement of $(\text{NaO})^+$ by $(\text{BaN})^+$). Doping this last host lattice with Eu^{2+} gives a blue-emitting phosphor enabling combination of a higher color rendering index with a high lumen output of a tricolor lamp (Jansen *et al.*, 1999) as compared to the commercial $\text{BaMgAl}_{10}\text{O}_{17}:\text{Eu}$ blue-emitting phosphor (which host lattice can be derived from $\text{NaAl}_{11}\text{O}_{17}$ by replacement of $(\text{NaAl})^{4+}$ by $(\text{BaMg})^{4+}$). Moreover, the presence of N^{3-} ions prevents the conversion of Eu^{2+} into Eu^{3+} , which is reported to be the main cause for the degradation of $\text{BaMgAl}_{10}\text{O}_{17}:\text{Eu}$ (Oshio *et al.*, 1998).

A number of additional new oxynitride and nitride phosphors have been recently developed by the $(\text{SiN})^+ \rightarrow (\text{AlO})^+$ or other replacements, also starting from basic structures different from the one of β -alumina (Yin *et al.*, 2014; Xia *et al.*, 2016; Cui *et al.*, 2017; Fang *et al.*, 2019). In many cases, these replacements (also referred to as chemical unit co-substitutions (Hoel *et al.*, 2010)) have led to improvements in the phosphor performance, such as better thermal stability of the emission intensity. In general, chemical unit co-substitution has become an emerging and valuable design strategy for the evolution of novel phosphors from existing ones.

Outlook

Since 1996, numerous materials belonging to the nitride and oxynitride families have proved to be excellent hosts for the development of efficient phosphors for white pcLEDs, emitting all over the visible range. In particular, phosphors emitting in the blue, green and red regions have been developed, employing various dopant rare earth ions, such as Ce^{3+} , Eu^{2+} , Tb^{3+} and Pr^{3+} , and using both allowed $5d \rightarrow 4f$ and forbidden $4f \rightarrow 4f$ transitions. However, the most important application of these doped materials is

in the field of Eu^{2+} -doped phosphors emitting in the red through $5d \rightarrow 4f$ transitions, usefully exploiting the strong crystal field splitting of the $5d$ orbitals and large covalency induced by the nitride ion N^{3-} , compared to simple oxide hosts. As an example, the recently developed $\text{Sr}[\text{Li}_2\text{Al}_2\text{O}_2\text{N}_2]:\text{Eu}^{2+}$ phosphor (Hoerder *et al.*, 2019) is an almost ideal material for pcLEDs. However, in the last years, competing red phosphors have been proposed and applied, especially fluoride host materials containing the $3d^3$ ion Mn^{4+} in octahedral coordination. In this hosts, the dopant ion is able to emit sharp bands in the useful red region around 632 nm in fluoride hosts, due to the ${}^2\text{E} \rightarrow {}^4\text{A}_2$ transition (Zhou *et al.*, 2018), upon excitation in the violet or blue regions. Moreover, halogen-based nanocrystalline lead perovskite materials have become additional candidates for the production of the red component in warm white light pcLEDs. A very significant review of the chemical and optical properties of the three prominent classes of red emitting materials $[\text{A}_2\text{MF}_6:\text{Mn}^{4+}]$ ($\text{A} = \text{K}, \text{Na}, \text{and Cs}$; $\text{M} = \text{Si}, \text{Ge}, \text{Zr}, \text{Sn}, \text{and Ti}$) and $\text{XSiF}_6:\text{Mn}^{4+}$ ($\text{X} = \text{Ba or Zn}$), the nitridoaluminate phosphor ($\text{Sr}[\text{LiAl}_3\text{N}_4]:\text{Eu}^{2+}$), and nanocrystals of cesium lead iodide perovskite (CsPbI_3) has been published a few years ago (Lin *et al.*, 2016). The race is still on for the development of the perfect phosphors for LEDs, and nitride and oxynitride materials will certainly play a very important role.

Introduction

The luminescent materials known as phosphors convert energy into electromagnetic radiation, usually in the visible energy range. As far as vacuum ultraviolet (VUV) optical excitations are concerned, the most suitable materials are the large band gap inorganic lattices activated by rare earth ions. These phosphors are mainly sintered oxo (phosphates, borates, aluminates, etc.), oxofluoride, or fluoride compounds. VUV optical excitations in these systems, ranging between soft X-rays and conventional UV, result either in a direct excitation of the luminescence center or an excitation of the host lattice, which will transfer part of the energy to the emitting levels of the activator.

The development of industrial applications in lighting and flat color display screens based on a xenon plasma discharge, which generates VUV radiation within an energy range of approximately 8.5 to 7 eV (145 and 180 nm), has induced a revival of interest in VUV-excited phosphors and in VUV spectroscopy using synchrotron radiation facilities. Both applications need very efficient and stable phosphors under ionizing conditions. In addition, mercury-free fluorescent lamps require, phosphors with a quantum yield higher than 1 (quantum cutters) in order to approach the energy efficiency of mercury excitation. There are some drawbacks in commercially available phosphors to be used in Hg-free lamps, which include low efficiency, easy degradation under VUV excitation, imperfect color coordinates, etc. Therefore, new phosphors that can efficiently convert VUV light into blue, green and red lights would be of great interest to the field. Besides applications in lighting and flat color display, VUV phosphors are also very suitable for scintillators. VUV scintillator has wide range of applications in medical imaging, nuclear physics, security scanning and astronomy. Some applications require very fast scintillation response which triggered the search for new materials in this area.

Excitations in the Rare Earth Center

Direct optical excitations of rare earth ions in the solid state occur via transitions between quasi-atomic states resulting from degeneracy removal of $^{2S+1}L_J$ free-ion levels by a spherical crystal field perturbation. In the $4f^n$ ground state configuration, transitions between crystal field levels are forbidden by the parity conservation rule and only small admixtures of wave functions of opposite parity into the $4f^n$ wave functions can induce f–f electric dipole transitions. Therefore, the 4f–4f intra-configuration transitions are forced electric dipole transitions, and consequently will appear in absorption and emission spectra as weak (the intensity is directly related to the degree of mixing) and very sharp bands. These two characteristics are in contrast to a strong absorption spread over a broad energy domain as required for efficient phosphors but, in compensation, the forced transitions between crystal field levels within the open f-shell give rise to relatively spectrally pure luminescence, the duration of which is convenient for phosphor applications in display devices. Therefore, rare earth ions are appropriate activators for such applications.

Trivalent rare earth compounds can also provide strong absorptions when energetic photons induce electron promotions from the $4f^n$ ground state toward d-states belonging to the first excited configuration, $4f^{n-1}5d$. Electric dipole transitions which occur between two configurations of opposite parity are Laporte allowed at first order. In general, they give rise to very intense absorption bands and, due to the greater radial extension of the d-orbitals, these bands are widely vibronic in character and very sensitive to crystal field interaction. The magnitude of the crystal field splitting of the fivefold orbitally degenerated 5d levels, and their coupling with the remaining $4f^{n-1}$ states, are therefore important factors to consider in phosphor modeling.

In rare earth phosphors, when UV or VUV radiations populate optically a 5d-state, radiative and/or nonradiative channels are available for energy relaxation in the solid state. Energy transfer to the emitting 4f-level occurs through lattice phonon relaxation and intra-system energy crossing when the energies match. The efficiency of the latter process depends upon the magnitude of the square overlap integrals between absorption and emission. Following the well-known configuration coordinate model, coordinate displacement between the equilibrium positions of the ground and 5d excited states, called the Franck–Condon shift, can be adjusted in phosphor design by choosing suitable host anionic groupings in order to fix the emission frequency or to increase the phosphor efficiency.

It is worthwhile considering that the variation of the energy of the lowest 4f–5d level versus the number of f-electrons in the shell follows the variation of $3+/4+$ redox potential along the lanthanide series. It is related to the ability of the trivalent rare earth ion to lose one electron and consequently to the stabilization energy of the $4+$ state.

Fig. 1 Energy scheme of exciton and free charge carriers recombination on rare earth impurity involving the autoionization states.

Absorption Involving the Doping Ion and Conduction Band States

In large band gap materials, the energy levels of the impurity center are sparsely distributed between the valence and conduction bands. This is especially true for trivalent rare earth ions with discrete quasiatomic states displayed within the large forbidden band gap of insulators (Fig. 1). In the combined host + rare earth impurity system, the VUV absorption can promote one electron from the ground state of the rare earth ion to excited 5d-states that overlap energetically the conduction band of the host. In the case of a strong coupling between these 5d-states and the continuum of the solid, the electron can be completely delocalized in the conduction band and the autoionization process of the rare earth ion occurs, giving rise to the $(\text{Ln}^{3+} + h^+) + e^-$ (free) state. The capture of the free-electron interpreted in the frame of the model of the exciton trapped on the impurity center as $(\text{Ln}^{3+} + h^+) + e^-$ (bounded) state, results in energy emission that corresponds to the excess of the exciton recombination energy. Part of this energy can be transferred to the 4f emitting level through, for example, dipole–dipole interaction in the case of allowed transitions or higher order multipole interactions for the quasi-forbidden ones.

The propensity of the rare earth ion to give up one electron should be regarded as its hole acceptor capability. It means that these ions embedded in a solid will develop a more or less intense short range potential for hole attraction depending upon the stabilization energy of the $4+$ state. This is the case for Ce^{3+} and Tb^{3+} with one more f-electron than, respectively, the empty and half shell.

Absorption Involving the Doping Ion and Valence Band States

In the VUV energy range, a charge transfer (CT) from the immediate rare earth ion neighbors to the impurity ion states can occur via electron delocalization from states having essentially a ligand character (2p in oxides and fluorides) and forming the valence band to states localized on the rare earth ion. This interaction results in $(\text{Ln}^{3+} + e^-) + h^+$ (free) state formation.

The electron transfer probability, for a given ligand, should be connected to the electron affinity of the rare earth ion, which depends on the degree of filling of the open f-shell. The electron affinity follows the $2 + 1/3 +$ redox potential variation along the lanthanide series according to the stabilization energy variation of the $2+$ state. It is easy to understand that Eu^{3+} with a $4f^6$ configuration will easily gain one electron in order to reach the $4f^7$ more stabilized configuration of the half-series. The same conclusion stands for Yb^{3+} with a $4f^{13}$ configuration.

In addition to the electron affinity of the metallic ion, the energy of the CT process depends strongly on the electronegativity of the ligand. Fluorides, for example, place this transition at the highest energy, much higher than oxides and sulfides and even higher than the 4f–5d transitions. For this reason and thanks to its high electron-affinity, the CT band of Eu^{3+} (Yb^{3+}), embedded in fluoride compounds, can be recorded easily.

The last consideration on the CT band energy position rests on the ligand–metal ion distance. Long distances accounting for ionic bondings provide high energy CT whereas more covalent bondings result in lower energy CT. For the same ligand, the CT energy depends on the coordination number, which determines the ligand–metal ion distance.

The recombination of the free hole with the electron bounded on the rare earth center provides energy that can be transferred to the rare earth radiative level.

When electron acceptors such as Sm^{3+} , Eu^{3+} , Tm^{3+} with a relatively high electron affinity are embedded in solids, they develop a short range potential to attract electrons. They are hole donors and the resulting excited CT state ($\text{Ln}^{2+} + \text{h}^+$) is generally well coupled to the lattice vibrations. Consequently, in the configuration coordinate model, the associated Franck–Condon shift of the CT state is larger than for d-states and of opposite sign. The CT state will relax via the common pathways: resonant or phonon assisted energy transfer, radiative and nonradiative relaxation, following the theoretical developments of Förster and Dexter whenever there is an overlap between emission and absorption.

Host-Sensitized Luminescence

When the energy of the incoming photons becomes higher than the fundamental absorption of the host, which corresponds to the excitonic absorption threshold, the luminescence excitation mechanisms are different. Compared to the direct absorption in the luminescence center, the fundamental or intrinsic absorption is two or three orders stronger in magnitude, and consequently, the quasi totality of the incoming VUV photons are absorbed by the lattice if we neglect the reflectivity. Excitation by a photon with energy greater than the band gap, E_g , results in the creation of a hot hole in the valence band and of a hot electron in the conduction band. Electrons and holes thermalize with a characteristic time of the order of 10^{-12} s and the energy lost for phonons during this step is of the order of 0.5 to $2 E_g$ per electron. Two main excitation mechanisms induced by thermalized electronic excitations are then possible: either radiative or nonradiative energy transfer from excitons or sequential hole and electron captures involving a charge transfer on the impurity center. The same impurity ion can undergo different mechanisms depending upon the electronic structure of the host crystal, the space distribution of secondary electronic excitations and the presence of additional electron and hole traps.

In the VUV phosphor applications, in order to obtain acceptable energy efficiencies, phosphors with quantum yield greater than 1 are highly desirable. Such a process can take place in so-called photon multiplication, in which the VUV photon absorbed by the host lattice can induce two or more visible photons of activator luminescence. This process is based on the effect of electronic excitations (EE) multiplication when the kinetic energy of the fast photoelectron or hole is enough for the creation of one or more other secondary electronic excitations as a result of inelastic scattering on valence or activator electrons. Before transferring their excitation energy to the luminescent centers, EEs also go through thermalization processes such as electron–electron inelastic scattering, electron–phonon interaction and energy migration through the lattice. The number of secondary EEs is determined by the ratio between the photon energy and the average energy necessary to create an EE: $E_{EE} = 1.5\text{--}3 E_g$. For insulators with a wide band gap and a narrow valence band, as is the case in fluorides, the multiplication threshold is close to $2 E_g$. In turn, in oxides where the width of the valence band (E_v) is of the order of the band gap, the multiplication threshold turns out to be $(2 E_g + E_v)$. The total phosphor efficiency depends on the efficiency of the secondary electronic excitation transfer mechanism from the crystalline host to the luminescence center and on the efficiency of the radiative relaxation in this center.

In addition to the materials and device development, understanding the luminescence mechanism is very important. To understand the underlined luminescence mechanism in rare-earth doped VUV phosphors, it is required to clarify the energy levels within the band gap of phosphor. While there may not be any energy level present in the pure host materials, doping with rare-earth elements give new or additional energy levels. Fig. 2 shows the photoluminescence (PL) and PL excitation (PLE) spectra of

Fig. 2 PL (a) and PLE (b) spectra of Ln^{3+} doped YAlO_3 . λ_{ex} and λ_{em} show excitation wavelength for PL and monitored emission wavelength for PLE, respectively. Marks of dashed lines indicate typical emission and excitation peaks. CT and HL peaks in PLE spectra were attributed to charge transfer transition and host lattice excitation, respectively. Reprinted from Shimizu, Y., Ueda, K., Inaguma, Y., 2017. Photoluminescence excitation spectra of lanthanide doped YAlO_3 in vacuum ultraviolet region. *Optical Materials* 66, 327–331, with permission from Elsevier.

Ln^{3+} (Nd, Eu, Gd, Tm) doped YAlO_3 samples to investigate the emission and excitation related energy level within the band gap of the host lattice. PL spectra shown in Fig. 2(a) were measured under the VUV photoexcitation at 157 nm. These are typically sharp peaks originated from 4f–4f transitions of Ln^{3+} ions. PLE spectra were obtained by monitoring luminescence at 314, 398, 460 and 615 nm in Gd^{3+} -, Nd^{3+} -, Tm^{3+} - and Eu^{3+} -doped samples, respectively. PLE peak at 157 nm (7.9 eV) was observed in all samples regardless of doping element. This peak is due to host lattice (HL) excitation as the band gap energy of host lattice is close to 8 eV. Broad shape peaks in the PLE spectra are assigned to CT peaks. The peak at 277 nm is due to 4f–4f transition.

In phosphor efficiency, there is an additional factor that should be taken into account, in the fundamental absorption region where the absorption coefficient is very high. In this region, the influence of the surface defects inducing surface losses is of prime importance in the luminescence quenching.

Conclusion

VUV phosphor still remains as one of the active research area in solid state luminescent materials due to its robustness and applications into the electronics and medical physics. Besides various applications, VUV phosphors are very good to study luminescence mechanism of rare earth ions in the ultraviolet region. Understanding luminescence mechanism will be helpful to design new phosphors in the emerging area of medical sciences and electronics.

Introduction

The status of emerging silicon carbide (SiC) wide-bandgap semiconductor electronics technology is briefly surveyed. SiC-based electronic devices and circuits are being developed for use in high-temperature, high-power, and/or high-radiation conditions under which conventional semiconductors cannot function (Buttay *et al.*, 2011). Projected performance benefits of SiC electronics are briefly illustrated for several applications. However, most of these operational benefits of SiC have yet to be realized in actual systems, primarily owing to the fact that the growth techniques of SiC crystals are relatively immature and device fabrication technologies are not yet sufficiently developed to the degree required for widespread, reliable commercial use. Key crystal growth and device fabrication issues that limit the performance and capability of high-temperature and/or high-power SiC electronics are identified. The electrical and material quality differences between emerging SiC and mature silicon electronics technology are highlighted.

Properties of SiC

Silicon carbide occurs in many different crystal structures, called polytypes. A comprehensive introduction to SiC crystallography and polytypism can be found in Powell *et al.* (1993). Despite the fact that all SiC polytypes chemically consist of 50% carbon atoms covalently bonded with 50% silicon atoms, each SiC polytype has its own distinct set of electronic properties. While there are over 100 known polytypes of SiC, only a few are commonly grown in a reproducible form acceptable for use as semiconductors. The most common polytypes of SiC being developed for electronics are 3C-SiC, 4H-SiC, and 6H-SiC (Pizzagalli, 2014). 3C-SiC, also referred to as β -SiC, is the only form of SiC with a cubic crystal structure. The noncubic polytypes of SiC are sometimes ambiguously referred to as α -SiC. 4H-SiC and 6H-SiC are only two of many possible SiC polytypes with a hexagonal crystal structure. Similarly, 15R-SiC is the most common of many possible SiC polytypes with a rhombohedral crystal structure.

Because some important electrical device properties are nonisotropic with respect to crystal orientation, lattice site, and surface polarity, further understanding of SiC crystal structure and terminology is necessary. As discussed more thoroughly in Powell *et al.* (1993), different polytypes of SiC are actually composed of different stacking sequences of Si–C bilayers (also called Si–C double layers), where each single Si–C bilayer can simplistically be viewed as a planar sheet of silicon atoms coupled with a planar sheet of carbon atoms. The plane formed by a bilayer sheet of silicon and carbon atoms is known as the basal plane, while the crystallographic c -axis direction, also known as the stacking direction or the [0001] direction, is defined normal to Si–C bilayer plane. Fig. 1 depicts schematically the stacking sequence of the 6H-SiC polytype, which requires six Si–C bilayers to define the unit cell repeat distance along the c -axis [0001] direction. The [1 $\bar{1}$ 00] direction depicted in Fig. 1 is often referred to as the a -axis direction. The silicon atoms labeled 'h' or 'k' in Fig. 1 denote Si–C double layers that reside in 'quasi-hexagonal' or 'quasi-cubic' environments with respect to their immediately neighboring above and below bilayers. SiC is a polar semiconductor across the c -axis, in that one surface normal to the c -axis is terminated with silicon atoms while the opposite normal c -axis surface is terminated with carbon atoms. As shown in Fig. 1, these surfaces are referred to as the 'silicon face' and 'carbon face,' respectively.

Owing to the differing arrangement of silicon and carbon atoms within the SiC crystal lattice, each SiC polytype exhibits unique electrical and optical properties. Some of the more important semiconductor electrical properties of the 3C, 4H, and 6H silicon carbide polytypes at room temperature are given in Table 1. More detailed electrical properties can be found in Choyke *et al.* (1997) and Pensl *et al.* (1998) and references therein. Even within a given polytype, some important electrical properties are nonisotropic, in that they are strong functions of crystallographic direction of current flow and applied electric field (e.g., electron mobility for 6H-SiC). Dopants in SiC can incorporate into energetically nonequivalent quasi-hexagonal (h) C-sites or Si-sites, or quasi-cubic (k) C-sites or Si-sites (only Si-sites are labeled h or k in Fig. 1). While all dopant ionization energies associated with various dopant incorporation sites should normally be considered for utmost accuracy, Table 1 lists only the shallowest ionization energies of each impurity.

For comparison, Table 1 also includes comparable properties of silicon and GaAs. Because silicon is the semiconductor employed in most commercial solid-state electronics, it is the yardstick by which other semiconductor materials must be evaluated against. To varying degrees the major SiC polytypes exhibit advantages and disadvantages in basic material properties compared to silicon. The most beneficial superior material properties of SiC over silicon listed in Table 1 are its wide bandgap energy, exceptionally high breakdown electric field, high thermal conductivity, and high carrier saturation velocity. The electrical device performance benefits that each of these properties enable are discussed in the next section, as are system-level benefits enabled by improved SiC devices.

Electronics Benefits of SiC

The wide bandgap energy and low intrinsic carrier concentration of SiC allow it to maintain semiconductor behavior at much higher temperatures than silicon, which in turn permits SiC semiconductor device functionality at these much higher temperatures. Semiconductor electronic devices function in the temperature range where intrinsic carrier concentrations are negligible so that conductivity is controlled by intentionally introduced dopant impurities. Furthermore, the intrinsic carrier concentration, n_i , is a fundamental prefactor to well-known equations governing undesired junction reverse-bias leakage currents. As temperature increases, intrinsic carriers increase exponentially so that undesired leakage currents grow unacceptably large, and eventually at still higher temperatures, the semiconductor device operation is overcome by uncontrolled conductivity as intrinsic carriers exceed intentional device dopings. Depending on specific device design, the intrinsic carrier concentration of silicon generally confines silicon device operation to junction temperatures less than 300°C . The much smaller intrinsic carrier concentration of SiC theoretically permits device operation at junction temperatures exceeding 800°C , and 600°C SiC device operation has been experimentally demonstrated for a few prototype SiC devices.

The high breakdown field and high thermal conductivity of SiC coupled with high operational junction temperatures theoretically permit extremely high power densities and efficiencies to be realized. The high breakdown field of SiC relative to silicon

enables the blocking voltage region of a power device to be roughly 10 times thinner and 10 times more heavily doped, permitting roughly a 100-fold decrease in the blocking region resistance. For device topology reasons discussed in [Bhatnagar and Baliga \(1993\)](#) and [Chow et al. \(1998\)](#), the high breakdown field and wide energy bandgap of SiC also enable much faster power switching than is possible in comparably volt-amp rated silicon power-switching devices. Therefore, SiC-based power converters can operate at higher switching frequencies with much greater efficiency (i.e., less switching energy loss). Higher switching frequency in power converters is highly desirable because it permits use of smaller capacitors, inductors, and transformers, which in turn can reduce overall system size and weight.

While the smaller on-resistance and faster switching of SiC help minimize energy loss and heat generation, the higher thermal conductivity enables more efficient removal of waste heat energy from the active device. Because heat energy radiation efficiency increases greatly with increasing temperature difference between the device and the cooling ambient, the ability of SiC to operate at high junction temperatures permits much more efficient cooling to take place, so that heatsinks and other device-cooling hardware (i.e., fan cooling, liquid cooling, air conditioning, etc.) typically needed to keep high-power devices from overheating can be made much smaller or even eliminated.

While the preceding discussion has focused on high-power switching for power conversion, many of the same arguments can be applied to devices used to generate and amplify radio-frequency (RF) signals used in radar and communications applications. In particular, the high breakdown voltage and high thermal conductivity coupled with high carrier saturation velocity allow SiC microwave devices to handle much higher power densities than their silicon or GaAs RF counterparts, despite the disadvantage in low-field carrier mobility of SiC ([Table 1; Weitzel and Moore, 1998](#)). The high power density reduces the number of devices required to generate large total RF powers needed for fixed-base high-power RF transmission applications, thus minimizing RF matching difficulties and cooling requirements to reduce the overall system size and cost. SiC RF transistors are not well suited for low-power products, such as handheld cell telephone units.

Uncooled operation of high-temperature and/or high-power SiC electronics would enable revolutionary improvements in aerospace systems. Replacement of hydraulic controls and auxiliary power units with distributed 'smart' electromechanical controls and sensors capable of harsh-ambient operation will lead to substantial jet-aircraft weight savings, reduced maintenance, reduced pollution, higher fuel efficiency, and increased operational reliability. SiC high-power solid-state switches will also afford large efficiency gains in electric power management and control. Performance gains from SiC electronics could enable the public power grid to meet the increased consumer electricity demand without building additional generation plants, and improve power quality and operational reliability through 'smart' power management. More efficient electric motor drives, enabled by improved SiC power devices, will benefit industrial production systems as well as transportation systems such as diesel-electric railroad locomotives, electric mass-transit systems, nuclear-powered ships, and electric automobiles and buses.

Hostile environment SiC semiconductor devices and ICs offer little advantage if they cannot be reliably packaged and connected to form a complete system capable of operating in such environments. With proper materials selection, modifications of existing IC packaging technologies appear feasible for nonpowerSiC circuit packaging up to 300 °C. Prototype electronic packages that can withstand over 1000 h of heat soaking without electrical bias at 500 °C have been demonstrated ([Salmon et al., 1998](#)). Harsh environment passive components, such as inductors, capacitors, and transformers, must also be developed for operation in demanding conditions before the full system-level benefits of SiC electronics can be successfully realized.

SiC Crystal Growth

At the start of the semiconductor electronics era, SiC was considered an early transistor material candidate along with germanium and silicon. However, reproducible wafers of reasonable consistency, size, quality, and availability at acceptable cost are a prerequisite for commercial mass production of semiconductor electronics. Because SiC sublimates instead of melting at reasonably attainable pressures, SiC cannot be grown by conventional seeded melt-growth techniques such as those employed in the manufacture silicon wafers. This prevented the realization of SiC crystals suitable for mass production of electronics until the late 1980s. Prior to 1980 experimental SiC electronic devices were mostly confined to small (typically $\sim 1 \text{ cm}^2$), irregularly shaped SiC crystal platelets grown as a by-product of the Acheson process for manufacturing industrial abrasives ([Acheson, 1892](#)) or by the Lely process ([Lely, 1955](#)).

There have also been numerous efforts, some of which are still ongoing, to grow heteroepitaxial single-crystal 3C-SiC layers on top of large-area wafer substrate materials such as silicon or sapphire. These efforts have always resulted in SiC layers with high densities of structural defects. While some limited semiconductor electronic devices and circuits have been implemented in 3C-SiC grown on silicon, the performance benefits of these electronics are severely limited to the point where almost none of the operational benefits of SiC over silicon have been realized.

[Tairov and Tsvetkov \(1978\)](#) established the basic principles of a modified seeded sublimation growth process for 6H-SiC. This process, also referred to as the modified Lely process, was a breakthrough for SiC in that it offered the first possibility of reproducibly growing acceptably large single crystals of SiC that could be cut and polished into mass-produced SiC wafers. The growth process is based on heating polycrystalline SiC source material to $\sim 2400 \text{ °C}$ under conditions where it sublimates into the vapor phase and subsequently condenses onto a cooler SiC seed crystal. This produces a somewhat cylindrical boule of single-crystal SiC that grows taller at a rate of a few millimeters per hour. The preferred orientation of the growth in the sublimation process is such that vertical growth of a taller cylindrical boule proceeds along the [0001] crystallographic *c*-axis direction (i.e.,

Fig. 2 Cross-sectional schematic representation of 'off-axis' polished SiC surface used for homoepitaxial growth. When growth conditions are properly controlled and there is a sufficiently short distance between steps, silicon and carbon adatoms impinging onto the growth surface find their way to steps where they bond and are incorporated into the crystal. Thus, ordered lateral 'step flow' growth takes place, which enables the polytype stacking sequence of the substrate to be exactly mirrored in the growing epilayer (reproduced (with modifications) by permission of IOP Publishing from 'Semiconductor Interfaces, Microstructures, and Devices: Properties and Applications,' 1993, pp. 257–93).

vertical direction in Fig. 1). Circular '*c*-axis' wafers with surfaces that lie normal (perpendicular) to the *c*-axis can then be sliced from the roughly cylindrical boule. Other growth orientations (such as along the *a*-axis) are also being investigated, but are not nearly as available and well developed as *c*-axis-grown wafer material.

After further development of the sublimation growth process, mass-produced sublimation-grown wafers (6H-SiC polytype, 2.5 cm diameter) became commercially available in 1989. The vast majority of SiC semiconductor electronics development has taken place since then. Other companies have subsequently entered the SiC wafer market, and sublimation-grown wafers of the 4H-SiC polytype have also been widely commercialized. *n*-Type, *p*-type, and semi-insulating SiC wafers of 2.5 to 5 cm in diameter are commercially available, and prototype wafers as large as 10 cm in diameter have been grown in the laboratory.

Wafer size, cost, and quality are all very critical to the manufacturability and process yield of mass-produced semiconductor microelectronics. Compared to commonplace silicon and GaAs wafer standards, 4H- and 6H-SiC wafers are small, expensive, and generally of inferior quality. However, such disparities are expected considering that silicon and GaAs wafers have undergone decades of commercial process refinement, and that SiC is an extraordinarily hard material making it very difficult to properly saw and polish.

Most SiC electronic devices are not fabricated directly in sublimation-grown wafers, but are instead fabricated in much higher quality epitaxial SiC layers that are grown on top of the sublimation-grown wafer. Therefore, the controlled growth of high-quality epilayers directly impacts on the realization of SiC electronic devices and circuits. An interesting variety of SiC epitaxial growth methods, ranging from liquid-phase epitaxy, molecular beam epitaxy, and chemical vapor deposition (CVD), have been investigated (Choyke *et al.*, 1997; Pensl *et al.*, 1998). The CVD growth technique is generally accepted as the most promising method for attaining epilayer reproducibility, quality, and throughputs required for mass production.

In the simplest terms, variations of SiC CVD are carried out by heating SiC substrates in a chamber with flowing silicon- and carbon-containing gases that decompose and deposit silicon and carbon onto the wafer allowing an epilayer to grow in a well-ordered single-crystal fashion under well-controlled conditions. Conventional SiC CVD epitaxial growth processes are carried out at substrate growth temperatures between 1400 and 1600 °C at pressures from 0.1 to 1 atm resulting in growth rates of the order of micrometers per hour (Powell and Larkin, 1997). Higher temperature (up to 2000 °C) SiC CVD growth processes are also being pioneered to obtain higher SiC epilayer growth rates of the order of hundreds of micrometers per hour (Kordina *et al.*, 1997).

Homoepitaxial growth, whereby the polytype of the SiC epilayer matches that of the SiC substrate, is accomplished by step-controlled epitaxy (Kimoto *et al.*, 1997). Step-controlled epitaxy is based on growing epilayers on an SiC wafer polished at an angle (called the 'tilt angle' or 'off-axis angle') of typically 3–8° off the (0001) basal plane, resulting in a surface with atomic steps and flat terraces between steps as depicted schematically in Fig. 2. When growth conditions are properly controlled and there is a sufficiently short distance between steps, silicon and carbon adatoms impinging onto the growth surface find their way to steps where they bond and are incorporated into the crystal. Thus, ordered lateral 'step flow' growth takes place which enables the polytypic stacking sequence of the substrate to be exactly mirrored in the growing epilayer. When growth conditions are not properly controlled or when steps are too far apart (as can occur with SiC substrate surfaces that are polished to within less than 1° of the basal plane), growth adatoms can nucleate and bond in the middle of terraces instead of at the steps, which leads to growth of poor-quality 3C-SiC (Kimoto *et al.*, 1997; Powell and Larkin, 1997). It is impractical to intentionally vary the polytype of SiC epilayers, so that heterojunction device structures have not been demonstrated using single-crystal SiC–SiC heterojunctions.

It is important to note that most as-grown SiC epilayers contain varying densities of undesirable defects and surface morphological features which affect SiC device processing and performance to varying degrees (Neudeck, 2000). Micropipes and closed-core screw dislocations originating in *c*-axis substrates propagate through subsequently grown epilayers. Nonideal epilayer surface features commonly observed include 'triangular inclusions,' 'growth pits,' and macrosteps formed by coalescence of multiple SiC growth steps (i.e., 'step bunching') during epitaxy. Pregrowth wafer polishing as well as growth initiation procedures have been shown to have a strong impact on the formation of undesirable epitaxial growth features (Powell and Larkin, 1997). Continued reduction of these defects will clearly help pave the way for increasingly capable SiC devices, especially devices for very high-power applications.

In situ doping during CVD epitaxial growth is primarily accomplished through the introduction of nitrogen (usually N₂) for *n*-type and aluminum (usually trimethyl- or triethylaluminum) for *p*-type epilayers. Some alternative dopants such as phosphorous, boron, and vanadium have also been investigated for *n*-type, *p*-type, and semi-insulating epilayers, respectively. While reasonable variation in epilayer doping can be achieved by strictly varying the flow of dopant gases, the site competition doping method

(Larkin, 1997) has enabled a much broader range of SiC doping to be accomplished. In addition, site competition epitaxy has also made moderate epilayer dopings more reliable and repeatable. Commercial epilayer thickness and doping tolerances are specified at 25 and 50%, respectively, while doping uniformities of 7% and thickness uniformities of 4% over 30 mm wafers have been reported in developmental research (Burk and Rowland, 1997).

SiC Device Fabrication

In order to minimize the development and production costs of SiC electronics, it is essential that SiC device fabrication takes advantage of existing silicon and GaAs wafer processing infrastructure as much as possible. Most of the steps necessary to fabricate SiC electronics starting from SiC wafers can be accomplished using somewhat modified commercial silicon electronics processes and fabrication tools. While 4H-SiC and 6H-SiC device processing methods are discussed in this section, these processes are generally applicable to other polytypes of SiC, except for the case of 3C-SiC grown on silicon where all processing temperatures need to be kept below the melting temperature of silicon ($\sim 1400^\circ\text{C}$).

Patterned Doping by Ion Implantation

The fact that diffusion coefficients of most dopants in SiC are negligibly small below $\sim 1800^\circ\text{C}$ is excellent for maintaining device junction stability, because dopants do not undesirably diffuse as the device is operated for long times at high temperatures. Unfortunately, however, this characteristic also precludes the use of conventional dopant diffusion, a highly useful technique widely employed in silicon microelectronics manufacturing, for patterned doping of SiC. Therefore, laterally patterned doping of SiC is almost exclusively carried out by ion implantation. This somewhat restricts the depth that most dopants can be implanted to less than $1\text{ }\mu\text{m}$ using conventional dopants and implantation equipment. Compared to silicon processes, SiC ion implantation requires a much higher thermal budget to achieve acceptable dopant implant electrical activation.

Summaries of ion implantation processes for various dopants can be found in (Pensl *et al.*, 1998). Most of these processes are based on carrying out implantation at elevated temperatures ($\sim 500\text{--}800^\circ\text{C}$) using a patterned high-temperature masking material. The elevated temperature during implantation promotes some lattice self-healing during the implant, so that damage and segregation of displaced silicon and carbon atoms does not become excessive, especially in high-dose implants often employed for ohmic contact formation. Co-implantation of carbon with *p*-type dopants has been shown to improve the electrical conductivity of high-dose *p*-type layers (Zhao *et al.*, 1997).

Following ion implantation, the patterning mask is generally stripped prior to carrying out a very high-temperature ($\sim 1200\text{--}1800^\circ\text{C}$) anneal, the purpose of which is to achieve maximum electrical activation of dopant ions. At higher implant anneal temperatures, the SiC surface morphology can seriously degrade as damage-assisted sublimation etching of the SiC surface begins to take place (Capano *et al.*, 1998). Because sublimation etching is driven primarily by loss of silicon from the crystal surface, annealing in silicon overpressures can be used to prevent surface degradation during high-temperature anneals. Such overpressure is often achieved by close proximity solid sources, such as using an enclosed SiC crucible with SiC lid and/or SiC powder near the wafer, or by annealing in a silane-containing atmosphere.

Contacts

All useful semiconductor electronics require conductive signal paths in and out of each device as well as conductive interconnects to carry signals between devices on the same chip and to external circuit elements that reside off-chip. While SiC itself is theoretically capable of high-performance operation under extreme conditions, such functionality is useless without contacts and interconnects that are also capable of operation under the same conditions to enable complete circuit functionality. The durability and reliability of metal-semiconductor contacts and interconnects are one of the main factors limiting the operational high-temperature limits of SiC electronics. Most reported SiC metallizations appear sufficient for long-term device operation at temperatures up to 300°C . Depending on the device structure and application, SiC Schottky diode reverse leakage currents generally become excessive at temperatures greater than 400°C . SiC ohmic and Schottky contacts to meet the demanding requirements needed for harsher environment operation (i.e., temperatures $>400^\circ\text{C}$, high current densities, and/or oxidizing environments) are a challenging topic of ongoing research activity.

Specific overviews of SiC metal-semiconductor contact technology can be found in Porter and Davis (1995), Crofton *et al.* (1997), and Saxena and Steckl (1998). There are both similarities and a few differences between SiC contacts and contacts to conventional narrow-bandgap semiconductors (e.g., silicon, GaAs). The same basic physics and current transport mechanisms that are present in narrow-bandgap contacts, such as surface states, Fermi pinning, thermionic emission, and tunneling, also apply to SiC contacts. A natural consequence of the wider bandgap of SiC is higher effective Schottky barrier heights. Analogous to narrow-bandgap contact physics, the microstructural and chemical state of the SiC-metal interface is crucial to contact electrical properties. Therefore, premetal deposition surface preparation, metal deposition process, choice of metal, and postdeposition annealing can all greatly affect the resulting performance of metal-SiC contacts. Because the chemical nature of the starting SiC surface is strongly dependent on surface polarity, it is not uncommon to obtain significantly different results when the same contact process is

applied to the silicon face surface as opposed to the carbon face surface. While Schottky contact barrier height does somewhat depend on metal–semiconductor work-function difference, the dependence is weak enough to suggest that surface state charge also plays a significant role in determining the effective barrier height of SiC Schottky junctions. Undesired nonuniformities in SiC surface properties owing to crystal defects and surface structure variations are widely suspected as the cause of uneven current flow and higher-than-expected leakage current barrier heights extracted by C – V methods typical in experimental SiC Schottky diodes. Thus, barrier heights extracted by C – V methods typically are higher than those extracted by I – V measurements.

While SiC specific ohmic contact resistances at room temperature are generally higher than in contacts to narrow-bandgap semiconductors, they are nevertheless sufficiently low for most envisioned SiC applications. Lower specific contact resistances are usually obtained to n -type 4H- and 6H-SiC ($\sim 10^{-4}$ – $10^{-6} \Omega \text{ cm}^2$) than to p -type 4H- and 6H-SiC ($\sim 10^{-3}$ – $10^{-5} \Omega \text{ cm}^2$). Consistent with narrow-bandgap ohmic contact technology, it is easier to make low-resistance ohmic contacts to heavily doped SiC. Regardless of doping, it is common practice with SiC to thermally anneal ohmic contacts to obtain the minimum possible contact resistance. Most SiC ohmic contact anneals are performed at temperatures around 900–1000 °C in nonoxidizing environments. Depending on the contact metallization employed, this anneal generally causes limited interfacial reactions (usually metal carbide or metal silicide formation) that broaden and/or roughen the metal–semiconductor interface.

Patterned Etching

At room temperature, no known wet chemical etches single-crystal SiC. Therefore, most patterned etching of SiC for electronic devices and circuits is accomplished using dry-etching techniques. Yih *et al.* (1997) give an excellent summary of dry SiC etching results. The most commonly employed process involves reactive ion etching (RIE) of SiC in fluorinated plasmas. Sacrificial etch masks (often metals) are deposited and photolithographically patterned to protect desired areas from being etched. The SiC RIE process can be implemented using standard silicon RIE hardware, and typical 4H- and 6H-SiC RIE rates are of the order of hundreds of angstroms per minute. Well-optimized SiC RIE processes are typically highly anisotropic with little undercutting of the etch mask, leaving smooth surfaces. One of the keys to achieving smooth surfaces is preventing ‘micromasking’ where masking material is slightly etched and randomly redeposited onto the sample, effectively masking very small areas on the sample that were intended for uniform etching. This can result in ‘grass’-like etch residue features being formed in the unmasked regions, which is undesirable in most cases. In special cases, RIE under conditions promoting micromasking is useful in greatly roughening the SiC surface to reduce the contact resistance of subsequently deposited ohmic metallizations.

While RIE rates are sufficient for many electronic applications, much higher SiC etch rates are necessary to delineate features of the order of tens to hundreds of micrometers deep that are needed to realize advanced sensors, microelectromechanical systems (MEMS), and some very high-voltage power device structures. High-density plasma dry-etching techniques, such as electron cyclotron resonance (ECR) and inductively coupled plasma (ICP), have been developed to meet the need for deep etching of SiC. Residue-free patterned etch rates exceeding 1000 Å min^{-1} have been demonstrated (Yih *et al.*, 1997).

Patterned etching of SiC at very high etch rates has also been demonstrated using photoassisted and dark electrochemical wet etching (Shor *et al.*, 1997). By choosing proper etching conditions, this technique has demonstrated a very useful dopant-selective etch-stop capability. However, there are major incompatibilities of the electrochemical process that make it undesirable for VLSI mass production, including extensive pre-etching and postetching sample preparation, etch isotropy and mask undercutting, and somewhat nonuniform etching across the sample.

Metal–Oxide–Semiconductor Technology

The vast majority of semiconductor integrated circuit chips in use rely on silicon metal–oxide–semiconductor field effect transistors (MOSFETs), whose electronic advantages and operational device physics are summarized in other elsewhere in this work. Given the extreme usefulness and success of MOSFET-based electronics in silicon, it is naturally desirable to implement high-performance inversion channel MOSFETs in SiC. Like silicon, SiC forms a thermal SiO_2 oxide when it is heated to high temperatures in an oxygen environment. While this enables SiC MOS technology to somewhat follow the highly successful path of silicon MOS electronics, there are nevertheless important differences in insulator quality and device processing that prevent SiC MOSFETs from realizing their full potential. While the following discussion attempts to quickly highlight key issues facing SiC MOSFET development, more detailed insights can be found in Afanasev *et al.* (1997), Brown *et al.* (1997), Cooper (1997), and Ouisse (1997). In highlighting the difficulties facing SiC MOSFET development, it is important to keep in mind that early silicon MOSFETs faced similar developmental challenges that took many years of dedicated research to overcome successfully.

From a purely electrical point of view, there are two prime operational deficiencies of SiC oxides and MOSFETs compared to silicon MOSFETs. First, effective inversion channel mobilities in most SiC MOSFETs are much lower (typically well under $100 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ for inversion electrons) than one would expect based on silicon inversion channel MOSFET carrier mobilities. This seriously reduces the transistor gain and current-carrying capability of SiC MOSFETs, so that they are not nearly as advantageous as theoretically predicted. Second, SiC oxides have not proved to be as reliable as well-developed silicon oxides, in that SiC MOSFETs are more prone to threshold voltage shifts, gate leakage, and oxide failures than comparably biased silicon MOSFETs. The excellent works by Cooper (1997) and Brown *et al.* (1997) discuss noteworthy differences between the basic electrical properties of n -type vs. p -type SiC MOS devices.

SiC MOSFET oxide electrical performance deficiencies appear to be mostly attributable to differences between silicon and SiC thermal oxide quality and interface structure that cause the SiC oxide to exhibit undesirably higher levels of interface state densities ($\sim 10^{11}$ – 10^{12} eV $^{-1}$ cm $^{-2}$), fixed oxide charges ($\sim 10^{11}$ – 10^{12} cm $^{-2}$), charge trapping, carrier oxide tunneling, and roughness-related scattering of inversion channel carriers. SiC surfaces are well known to be much rougher than silicon surfaces, owing to off-angle polishing needed to support SiChomoepitaxy as well as step-bunching that can occur during SiC homoepilayer growth. The wide bandgap of SiC reduces the potential barrier impeding tunneling of carriers into SiC thermal oxides, so that perfectly grown oxides on atomically smooth SiC are not be as reliable as silicon thermal oxides (Agarwal *et al.*, 1997). Therefore, it is highly probable that alternative gate insulators will have to be developed for optimized implementation of inversion channel SiC FETs for the most demanding high-power and/or high-temperature electronic applications.

Prototyping and Production of SiC Electronic Devices

This section briefly summarizes a variety of experimentally realized SiC electronic devices broken down by major application areas. The operational performance of experimental SiC devices is compared to that predicted theoretically as well as the capabilities of existing silicon and GaAs devices. SiC process and materials technology issues limiting the capabilities of various SiC device topologies are highlighted as key issues to be addressed in further SiC technology development.

Optoelectronics and Sensors

The wide bandgap of SiC is useful for realizing short-wavelength blue and UV optoelectronics. 6 H-SiC-based blue p–n junction light emitting diodes (LEDs) were the first SiC-based devices to reach high-volume commercial sales. These epitaxially grown, dry-etch, mesa-isolated p–n junction diodes were the first mass-produced LEDs to cover the blue (~ 250 – 280 nm peak wavelength) portion of the visible spectrum. Because the bandgap of SiC is indirect (i.e., the conduction minimum and valence band maximum do not coincide in crystal momentum space), luminescent recombination in the LEDs is governed by inherently inefficient indirect transitions mediated by impurities and phonons. Therefore, the efficiency of SiC blue LEDs is limited to well below 1%. While commercially successful from 1989 to 1995, SiC-based blue LEDs have been totally replaced by the emergence of much brighter, more efficient direct-bandgap GaN blue LEDs.

SiC has proved to be much more efficient at absorbing short-wavelength light, which has enabled the realization of SiC UV-sensitive photodiodes that serve as excellent flame sensors in turbine-engine combustion monitoring and control (Brown *et al.*, 1998). The wide bandgap of 6H-SiC is useful for realizing low photodiode dark currents, as well as sensors that are blind to undesired near-IR wavelengths produced by heat and solar radiation. Commercial SiC-based UV flame sensors, again based on epitaxially grown, dry-etch, mesa-isolated 6H-SiC p–n junction diodes, have successfully reduced harmful pollution emissions from gas-fired ground-based turbines used in electrical power generation systems.

The high-temperature capabilities of SiC allow the production of catalytic metal–SiC and metal–insulator–SiC (MIS) prototype gas sensor structures with great promise for combustion engine emission monitoring applications (Lloyd Spetz *et al.*, 1997; Hunter *et al.*, 1998). High-temperature operation of these structures, not possible with silicon, enables rapid detection of changes in hydrogen and hydrocarbon content to sensitivities of parts per million in very small sensors that could easily be placed unobtrusively anywhere in an engine. Once they have been more fully developed, these sensors could assist in active combustion control to reduce harmful pollution emissions from automobile and aircraft engines. While generally beyond the scope of this chapter, SiC is also likely to play a significant role in emerging MEMS applications (Mehregany *et al.*, 1998).

RF Electronics

The main use of SiC RF devices appears to be in high-frequency solid-state high-power amplification at frequencies from around 600 MHz (UHF band) to perhaps around 10 GHz (X band). As discussed by Weitzel and Moore (1998), the high breakdown voltage and high thermal conductivity coupled with high carrier saturation velocity allow SiC RF transistors to handle much higher power densities than their silicon or GaAs RF counterparts, despite the disadvantage of SiC in low-field carrier mobility (Table 1). The higher breakdown field of SiC permits higher drain breakdown voltage, allowing RF operation at higher drain biases, which leads to higher SiC MESFET output power densities. The higher thermal conductivity of SiC is also crucial in minimizing channel self-heating so that phonon scattering does not seriously degrade channel carrier velocity and current. Similar RF output power arguments can be made for SiC-based static induction transistors (SITs). While 4H-SiC MESFETs for high-power RF applications are now commercially available, increasingly beneficial SiC RF transistors should continue to evolve as SiC crystal quality and device processing technology continue to improve.

In addition to high-power RF transistors, SiC mixer diodes show excellent promise for reducing undesired intermodulation interference in RF receivers (Fazi and Neudeck, 1998). More than 20 dB dynamic range improvement has been demonstrated using nonoptimized SiC Schottky diode mixers. Such dynamic range improvement could prove particularly beneficial to RF systems where numerous receivers and high-power transmitters are closely located, such as on a commercial passenger aircraft or military surface ship.

High-Temperature Devices and ICs

Commercially available silicon-on-insulator circuits can perform complex digital and analog signal-level functions up to 300 °C when high-power output is not required. Thus, aside from ICs where it is advantageous to combine signal-level functions with high-power or unique SiC sensors/MEMS onto a single chip, more expensive SiC circuits solely performing low-power signal-level functions appear largely unjustifiable for low-radiation applications at temperatures below 250–300 °C. In high-power systems, junction self-heating and high electrothermal stress mean silicon devices cannot function above 100–200 °C. Thus, the transition to SiC is necessary at lower temperatures in high-power applications.

Achieving long-term operational reliability is the primary ongoing challenge of realizing 300–600 °C SiC devices and circuits. IC device technologies covered in other chapters in this work that have been used to successfully implement circuits in silicon and GaAs are to varying degrees candidates for use as a basis for SiC integrated circuits at $T > 300$ °C. High-temperature gate-insulator reliability, discussed in the section on SiC device fabrication, is needed for the successful realization of MOSFET-based integrated circuits. Gate-to-channel Schottky diode leakage limits the peak operating temperature of SiC MESFET circuits to around 400 °C. Prototype bipolar SiC transistors exhibit poor gains, but improvements in SiC crystal growth and surface passivation could greatly improve SiC BJT gains to make SiC bipolar devices a more viable technology (Wang *et al.*, 1996). As discussed previously, a common obstacle to all technologies is reliable long-term operation of contacts, interconnects, passivation, and packaging at $T > 300$ °C. Robust circuit designs that accommodate large changes in device operating parameters with temperature will be necessary for circuits to function successfully over the very wide temperature ranges (as large as 650 °C spread) enabled by SiC. Device behaviors that have traditionally been unimportant to design and simulation of silicon-based device and circuits, such as freezeout of incompletely ionized dopant atoms, must now be included for proper design and simulation of SiC devices and circuits. Because of carrier freezeout effects, it may prove difficult to realize SiC-based ICs operational at temperatures much lower than -55 °C.

Because signal-level circuits are operated at relatively low electric fields well below the electrical failure voltage of most micropipes, micropipes affect signal-level circuit process yields to a much lesser degree than they affect high-field power device yields. Small-scale prototype logic and analog amplifier SiC-based ICs have been demonstrated using SiC variations of common device topologies (Harris *et al.*, 1994; Xie *et al.*, 1994; Diogu *et al.*, 1996; Brown *et al.*, 1997; Ryu *et al.*, 1998). These prototypes are not commercially viable, largely owing to their high cost, unproven reliability, and limited temperature range that is mostly covered by silicon-on-insulator circuitry. However, increasingly capable and economical SiC integrated circuits will continue to evolve as SiC crystal growth and device fabrication technology continue to improve. Nonidealities in SiC epilayers, such as variations in epilayer doping and thickness, surface morphological defects, and slow charge trapping/detrapping phenomena causing unwanted device I – V drift, limit the yield, size, and manufacturability of SiC high-temperature ICs (Brown *et al.*, 1997).

High-power Switching

While SiC devices offer large potential benefits to high-power systems, solid-state devices in these systems are also the most susceptible to deficiencies in SiC material quality and process variations. This is primarily because these devices operate at high electric fields and high current densities that place the greatest electrical stresses on the semiconductor and surrounding device materials. Prototype SiC devices have demonstrated excellent area-normalized performance often well beyond (more than 10 times) the theoretical power density of silicon power electronics. However, the presence of crystal defects such as micropipes has prevented scale-up of small-area prototypes to large areas that can reliably deliver high total operating currents in large-scale power systems. Since the early 1990s SiC micropipe densities have dropped from hundreds to several tens per square centimeter of wafer area, resulting in corresponding improvements in peak SiC device operating currents from less than 1 A to several tens of amps. However, further defect reductions of at least an additional order of magnitude will be necessary before commercially viable power device yields at these current ratings can be expected.

In addition to micropipes, the density of nonhollow core (elementary) screw dislocation defects in SiC wafers and epilayers has been measured to be of the order of several thousand per square centimeter of wafer area. While these defects are not nearly as detrimental to device performance as micropipes, experiments have shown that they degrade the local material properties such as breakdown field and minority carrier lifetime (Neudeck, 2000). While localized breakdown is well known to degrade silicon device reliability in high-power switching applications, the exact impact on SiC high-power switching devices remains to be quantified. The electrical significance of other dislocation defects, if any, also remains to be ascertained.

For SiC power devices to function successfully at high voltages, peripheral breakdown owing to edge-related electric field crowding must be avoided through careful device design and proper choice of insulating/passivating dielectric materials. The peak voltage of most prototype high-voltage SiC devices has been limited by edge-related breakdown (often destructive), especially in SiC devices capable of blocking multiple kilovolts. In addition, most testing of multikilovolt SiC devices has required the device to be immersed in specialized high-dielectric fluids or gas atmospheres to minimize damaging electrical arcing and surface flashover at device peripheries. A variety of edge termination methods, many of which were originally pioneered in silicon high-voltage devices, have been applied to prototype SiC power devices with varying degrees of success. The higher voltages and higher local electric fields of SiC power devices will place larger stresses on packaging and on-wafer insulating materials, so it is unclear whether traditional materials used to insulate/passivate silicon high-voltage devices will prove sufficient for reliable use in SiC high-voltage devices, especially if those devices are to be operated at high temperatures.

The high-power diode rectifier is a critical building block of power conversion circuits. The most important SiC diode rectifier device design tradeoffs roughly parallel well-known silicon rectifier tradeoffs, except for the fact that numbers for current densities, voltages, power densities, and switching speeds are typically much higher in SiC. The high breakdown field of SiC and wide energy bandgap permit operation of SiC metal–semiconductor Schottky diodes at much higher voltages (i.e., kilovolts) and current densities than is practical with silicon-based Schottky diodes. For blocking voltages up to around 3 kV, unipolar SiC Schottky rectifiers appear to offer lower turn-on voltages ($\sim 1\text{--}2$ vs. ~ 3 V) and faster switching speeds (owing to no appreciable minority carrier injection/charge storage) than SiC p–n junctions (Chow *et al.*, 1998). In rectifiers that block over ~ 3 kV, bipolar minority carrier charge injection (i.e., conductivity modulation) should enable SiCp–n diodes to carry higher current densities than unipolar Schottky diodes whose drift regions conduct solely using dopant-atom majority carriers. Hybrid Schottky/p–n rectifier structures first developed in silicon that combine p–n junction reverse blocking with low Schottky forward turn-on should prove extremely useful to realizing application-optimized SiC rectifiers (Dahlquist *et al.*, 1998; Held *et al.*, 1998). As with silicon bipolar devices, reproducible localized control of minority carrier lifetime will be important in optimizing switching speed vs. ON-state current density performance. SiC minority carrier lifetimes of the order of several microseconds have been measured in high-quality epilayers (Kordina *et al.*, 1996), and lifetime reduction via intentional impurity incorporation and introduction of radiation-induced structural defects appears feasible.

Three terminal power switches that use small drive signals to control large voltages and currents are also critical building blocks of high-power conversion circuits. As summarized by Chow *et al.* (1998), a variety of prototype three-terminal SiC power switches have been demonstrated. For the most part SiC solid-state switches are based on well-known silicon device topologies, like the thyristor, vertical and lateral channel MOSFETs, IGBTs, etc., that try to maximize power density via vertical current flow using the substrate as one of the device terminals. Because these switches all contain high-field junctions responsible for blocking current flow in the off state, their maximum operating currents are primarily restricted by the material quality deficiencies discussed previously.

Silicon power MOSFETs and IGBTs are extremely popular in power circuits largely because their MOS gate drives are well insulated and require little drive signal power, and the devices are ‘normally off’ in that there is no current flow when the gate is unbiased at 0 V. However, as discussed previously, the performance and reliability of SiC power device structures with inversion channel MOS field-effect gates (i.e., MOSFETs, IGBTs, etc.) are limited by poor inversion channel mobilities and questionable oxide reliability at high temperatures. Thus, SiC device structures that do not rely on high-quality gate oxides, such as the thyristor, appear favorable for more immediate realization, despite some nontrivial drawbacks in operational circuit design and switching speed.

Some nontraditional power switch topologies have been proposed to somewhat alleviate SiC oxide and material quality deficiencies while maintaining normally off insulated gate operation. Lateral and vertical doped-channel power SiC MOSFETs and JFETs that can be completely depleted by built-in potentials at zero gate bias so that they are ‘normally off’ have been demonstrated. With the assistance of lateral surface electric field tailoring techniques, Baliga (1996) has suggested that lateral-conduction SiC power devices could deliver better power densities than traditional vertical SiC power device structures. Baliga also proposed advantageous high-voltage switching by pairing a high-voltage SiC MESFET or JFET with a lower voltage silicon power MOSFET.

Further Information

Many of the chapters on Semiconducting Devices in this work contain useful background on a variety of basic semiconductor device structures, the SiC versions of which are described here. In addition to the works referred to in this chapter, the readers are advised to see the following review paper (Buttay *et al.*, 2011) on SiC power electronic devices.

Scintillator Crystals

Physical Effect and Construction of Devices

Scintillators perform the transformation of high energy radiation into visible light. Most contemporary scintillator crystals (SCs) are either halides or oxides; an overview is given in [Table 1](#). Desirable properties for SCs are high transformation efficiency, stability under the working conditions and high optical transparency. These requirements are best met by crystals with low point defect density.

High energy radiation such as α -, β -, γ -, X-rays, protons, or neutrons can interact with matter and exchange energy (inelastic interaction). The main type of interaction depends on the energy E_0 of the radiation. The photoelectric effect prevails for $E_g < E_0 < 300$ keV (E_g =energy gap), whereas Compton scattering can usually be observed at higher $E_0 > 300$ keV. Moreover, the direct transformation of energy into matter (electron–positron pair formation) becomes possible for $E_0 > 1.022$ MeV. Different scintillating amorphous materials (glasses, plastics) and crystals perform the conversion of high energy radiation into visible light with wavelength around 400 nm ($E_1 \approx 3$ eV).

The conversion proceeds in multiple steps by the repeated interaction with the scintillator material ([Fig. 1](#)), where the energy of photons is reduced by multiple interaction from E_0 to E_1 . The examination of the visible light is often possible by the naked eye; photo multiplier tubes (PMT) or photodiodes are alternative light detectors. The number of photo-electrons (ph-e⁻) N that can be registered by the light detector grows with increasing E_0 . The theoretical upper limit $N = E_0/E_1 \approx 3 \times 10^5$ for $E_0 = 1$ MeV cannot be reached as a part of the incoming energy is wasted in nonradiative processes. The light yield for the highly effective scintillator crystal CsI(Tl) is $N \approx (5...6) \times 10^4$ ph-e⁻ MeV⁻¹ (cf. [Table 2](#)). Some ‘modern’ materials such as BaBrI ([Bouret-Courchesne et al., 2010](#)) are not daltonide compounds with fixed stoichiometry, but solid solutions (in this case between BaI₂ and BaBr₂). Especially compounds of the heavier halogens bromine and iodine, such as SrI₂, are often very hygroscopic or sensitive against oxygen and crystal growth as well as subsequent handling require special care ([Guguschev et al., 2014](#)).

One crucial property of the scintillator is the absorption coefficient α . It allows to describe the loss of intensity $I(E_0) = I_0 \exp[-\alpha z]$ of the incoming radiation of energy E_0 within the material depth z . At the absorption edge ($E > E_g$) the absorption reaches values of typically $\alpha = (10^5...10^6)$ cm⁻¹. For energies far above E_g the coefficient was found to drop according to the empirical relation $\alpha \sim Z_{\text{eff}}^4/E_0^3$ ($Z_{\text{eff}} = Z - \sigma_n$ is the average effective atom number, $\sigma_n \ll Z$ is the shielding due to electrons). Materials that contain atoms with high Z numbers are especially suitable for scintillator applications. Information on the spectral composition of the incident radiation can be obtained from the time dependent spectra of the emitted light (decay time of light intensity τ_d).

Particles with energy of about 100 keV can give rise to X-ray transitions, if elements with high atomic number are present within the material. The lifetime of excited states is usually short ($\tau \approx 10^{-15}$ s) and results, due to the Heisenberg relation $\Delta E \cdot \tau \geq \hbar$, in natural line widths of $\Delta E \approx 1$ eV. Desirable properties are:

Table 1 Scintillator crystals

Full name	Chemical formula	Abbreviation
Cesium iodide (Tl doped)	CsI(Tl)	–
Cesium fluoride	CsF	–
Sodium iodide (Tl doped)	NaI(Tl)	–
Calcium fluoride (Eu doped)	CaF ₂ (Eu)	–
Barium chloride	BaCl ₂	(ceramic)
Barium fluoride	BaF ₂	–
Strontium iodide	SrI ₂	–
Lanthanum bromide	LaBr ₃ (Ce, Ba)	–
Bismuth germanate	Bi ₄ Ge ₃ O ₁₂	BGO
Bismuth silicate	Bi ₄ Si ₃ O ₁₂	BSO

Cadmium tungstate	CdWO ₄	CWO
Yttrium aluminate (Ce doped)	YAlO ₃ (Ce)	YAP(Ce) = YALO(Ce)
Lutetium aluminate (Ce doped)	LuAlO ₃ (Ce)	LuAP(Ce)
Gadolinium orthosilicate (Ce doped)	Gd ₂ SiO ₅ (Ce)	GSO(Ce)
Lutetium orthosilicate (Ce doped)	Lu ₂ SiO ₅ (Ce)	LSO(Ce)
lutetium yttrium orthosilicate	Lu _{≈0.6} Y _{≈1.4} SiO ₅ (Ce)	LYSO(Ce, Ca)
Zinc sulfide	ZnS	–
Cadmium telluride	CdTe	–

Fig. 1 Principle of a scintillator detector. Usually photo multiplier tubes (PMT) or photodiodes are used as light detector.

Table 2 Melting temperature, density, effective Z number, emission maximum, photoelectron yield and decay time for some halide scintillator crystals

	T_m ($^{\circ}\text{C}$)	ρ (g cm^{-3})	Z_{eff}	$\lambda_{\text{em}}^{\text{max}}$ (nm)	yield ($\text{ph-e}^{-}/\text{MeV}$)	τ_d (ns)
CsI(Tl)	621	4.51	54	550	52 000...56 000	3500/600
NaI(Tl)	651	3.67	50	415	38 000	230
$\text{CaF}_2(\text{Eu})$	1418	3.18	17	435	19 000	940
BaF_2	1354	4.88	53	310	10 000	630/0.8
CsF	682	4.63	53	390	2000	5
$\text{BaBr}(\text{Eu})$	>710	5.2		413	$81\,000 \pm 3000$	297/482

- Emission maximum close to 400 nm to match the maximum sensitivity of PMTs.
- Refractive index close to 1.5 to obtain maximum optical coupling to the PMT input window that is usually made of glass.
- Short τ_d to obtain good temporal resolution.
- High absorption for the incident radiation.
- High conversion rate from E_0 to E_1 with low nonradiative background.
- Low absorption for the generated light.
- Stability under harsh working conditions (hard radiation, high T , mechanical shocks).

In low Z materials as plastics or some glasses, the Compton effect dominates over a broad range ($20 \text{ keV} \lesssim E_0 \lesssim 10 \text{ MeV}$) and no single peaks can be observed in the spectrum. Accordingly, low Z scintillators are used if no energy information of the incidenting radiation is needed. In the following, only crystalline scintillator materials will be considered.

Growth of SCs

The growth of crystals with applications in high energy radiation will not be discussed here in detail, but the main scintillators are listed below for sake of completeness:

- (a) ZnS. For SC applications the material is often doped with Ag. The typical photoelectron yield is ca. 25% of NaI(Tl) for γ radiation. The material is often used as polycrystalline powder for screens. Single crystals can be obtained by gas phase transport. Growth from the melt is difficult, as ZnS melts only under high pressure at $T_m^{\text{ZnS}} \simeq 1800^{\circ}\text{C}$. Depending on the crystallization conditions, ZnS crystallizes either in the hexagonal wurtzite or in the cubic zincblende structure. As the difference between both structures consists only in a different stacking of Zn-S planes, poly-types are rather frequent.
- (b) ZnSe, CdTe. Gas phase transport, Vertical Bridgman (VBr), or traveling heater method (THM) crystals of both chalcogenides and of solid solutions (Cd, Zn)Te with high resistivity are used as detectors for high energy radiation (security screening, astrophysical research).

The application of different SCs is often restricted by the available crystal size. The requirements for a crystal to be used as scintillator include a size of typically at least $1 \times 1 \times 1 \text{ cm}^3$ and a sufficiently high absorption $\alpha(E_0) \gtrsim 0.1 \text{ cm}^{-1}$. Such requirements can be met by nearly all substances mentioned here. On the other hand, imaging techniques such as positron emission tomography (PET), computer tomography (CT), X-ray telescopes or luggage scanning need either arrays of up to 10 000 SCs or larger crystals of up to ca. 50 cm diameter.

Table 3 Melting temperature, density, effective Z number, emission maximum, photoelectron yield and decay time for some oxide scintillator crystals

	T_m (°C)	ρ (g cm ⁻³)	Z_{eff}	λ_{em}^{max} (nm)	yield (ph-e ⁻ /MeV)	τ_d (ns)
Bi ₄ Ge ₃ O ₁₂	1050	7.13	75	480	8 000...10 000	300/60
PbWO ₄	1120	8.28	73	420	11...14	30/2
CdWO ₄	1325	7.9	65	470	12 000...15 000	14 000
YAlO ₃ (Ce)	1875	5.55	36	350	18 000	27
LuAlO ₃ (Ce)	1910	8.34	65	350	14 000	18
Gd ₂ SiO ₅ (Ce)	1950	6.71	59	430	12 500	60
Lu ₂ SiO ₅ (Ce)	2150	7.41	66	420	25 000	40

SCs are used for the registration of hard radiation. This hard radiation can lead to the formation of structural defects in the crystal and therefore to damage of the detector. Usually point defects (vacancies, interstitials) are produced, if the kinetic energy that is transferred from the incident particle or photon to one atom of the crystal exceeds the binding energy of this atom. Crystal structures with 'heavy' atoms have not only the advantage of high α but also of the high inertia of these high Z atoms. Generally, the lattice energy and therefore the activation energy for the formation of structural defects is positively correlated with the melting point. Therefore the most stable (with respect to radiation hardness) SCs are found among the oxides with extremely high T_m mentioned in [Table 3](#).

Chemical purity (absence of contaminants besides intended doping) of the SCs is very important for radiation hardness, as the local inhomogeneity around extrinsic point defects formed by foreign atoms usually lowers the activation energy for the formation of more extended defects as vacancy clusters. On the other hand; extended defects such as dislocations or even grain boundaries do often not prevent effective scintillation. For example, BGO scintillates as single crystal, as thin film, and even as ceramic material. The absence of extended defects is important, if scintillation light from large crystal volumes has to be collected within a light detector. Otherwise intrinsic light loss by scattering would reduce the yield of the SC.

SCs are usually grown from the melt by the VBr or Czochralski (Cz) methods. For data sheets and general reading about radiation measurements the reader is reminded to the homepage of 'Saint-Gobain Crystal Scintillation Products' [Saint-Gobain \(2015\)](#). Recommended review articles on SCs are by [Ishii and Kobayashi \(1992\)](#), [Melcher et al. \(1991\)](#), and more recently by [Yoshikawa et al. \(2013\)](#).

Halides

Halide crystals for scintillators and other optical applications are usually grown by VBr, but the growth by Cz was reported too. [Gugushev et al. \(2014\)](#) reported the application of floating dies, for example, of graphite for halide crystal pulling, which help to stabilize the shape of the growing crystal. For large SCs with volumes of ≥ 1000 cm³ extreme purity is especially important for obtaining high transparency in the optical region. Otherwise, the scintillation light would not reach the SC surface. As VBr works usually with smaller T gradients G_T than Cz, the former method provides large halide crystals with reduced thermal stresses. Graphite is chemically inert to halide melts and is usually applied for crucibles and constructive parts.

An interesting method for the pulling of large alkali halide crystals (diameter ≤ 450 mm, mass ≤ 300 kg, pulling rate ca. 6 mm h⁻¹) was reported by [Zaslavsky \(1999\)](#). In this method, a conical platinum crucible is connected to a feeder containing the molten starting material. The melt is supplied to the conical crucible using an inert gas pressure. As the melt height in the crucible is set to exceed only slightly the actual diameter of the growing crystal, the free surface of the melt is very small, leading to negligible evaporation losses of the activator thallium.

Halides are, typically in the order $I^- < Br^- < Cl^- < F^-$, sensitive against hydrolysis with traces of moisture that can be present in the starting materials or in the growth atmosphere. At $p_{total} = 1$ bar and $T = 690$ °C (69 K above $T_m^{(CsI)}$ or 8 K above $T_m^{(CsF)}$, respectively), the chemical reactions

where (X=I, F) have the following equilibrium constants:

$$K^{(CsX)} = \frac{[CsOH][HX_{(gas)}]}{[CsX][H_2O_{(gas)}]} \quad [2]$$

$K^{(CsI)} = 2.4 \times 10^{-10}$ and $K^{(CsF)} = 1.1 \times 10^{-5}$. Graphite is an advantageous crucible material for halides, as the chemical reaction

helps to remove water from the system and thus to avoid hydrolysis (1). If carbon is heated under wet Ar (1 ppm H₂O) up to the T_m of CsI, NaI, or CsF (600 °C range), then $p_{H_2O} \gg 10^{-6}$ bar drops from 10^{-6} bar to a few 10^{-12} bar. Upon heating to the melting point of CaF₂ (1418 °C) $p_{H_2O} \gg 10^{-15}$ bar, thus drastically reducing the fluoride hydrolysis.

The earth alkali fluorides CaF₂ and BaF₂ exhibit considerably higher melting points as compared to the alkali halides. Melting can lead therefore to the transformation of hydroxides into oxides. As the solubility of the oxides in the fluoride crystals is small, scattering centers (precipitates) that decrease the optical transparency may form. Moreover, the highly reductive conditions within the graphite crucibles can lead to the reduction $Me^{2+} \rightarrow Me^+ \rightarrow Me$ and to the formation of color centers. In the following the main properties of halides are outlined:

NaI(Tl), CsI(Tl) NaI(Tl) is the most common SC due to its high visible light yield; the crystals convert about 12% of the γ -ray energy into $E_1 = 3$ eV photons. Cesium iodide and sodium iodide (undoped and more often doped with Tl) are grown up to 50 cm in diameter by VBr. Both substances are at least slightly hygroscopic. The emission maximum at 550 nm is not well matched to the maximum sensitivity of PMTs but rather to the sensitivity of photodiodes.

CsF is an effective SC with short τ_d ; but unfortunately very hygroscopic.

BaF₂, CaF₂(Eu) Both cubic crystals are usually grown under vacuum (to reduce $p_{H_2O} \gg 10^{-6}$ bar) by VBr from graphite crucibles. BaF₂ is the fastest known scintillator. Its scintillation exhibits two decay constants that may be used to obtain spectral resolution of the incident radiation, as the ratio between both components depends on the ionizing ability of the incident radiation. CaF₂ is a slow SC. Its low $Z_{eff}^{CaF_2} = 17$ (as compared to $Z_{eff}^{BaF_2} = 53$) makes calcium fluoride an ideal material for the detection of β -particles.

Oxides

Oxides in the oxidation state m are always in equilibrium with some finite oxygen partial pressure $p_{O_2}^{eq}$. If p_{O_2} the ambient is $> p_{O_2}^{eq}$, through the reaction

the higher valent $MeO_{(m+1)/2}$ can be formed. As $p_{O_2}^{eq}$ rises with T , higher p_{O_2} have to be maintained for very high melting oxides. Ellingham diagrams represent the stability ranges for the oxides with different valencies that are nearly linear in the $T - RT \ln p_{O_2}$ plane. For more details the reader is referred to [Pelton \(1991\)](#) and [Klimm et al. \(2009\)](#). **Fig. 2** gives an overview on the $p_{O_2}^{eq}(T)$ for different pure oxides and provides an estimation about the stability range of mixed oxide melts. An annealing treatment under defined p_{O_2} adjust the valency of some metal ions (e.g., Pb^{2+} in the case of PWO) to the desired level.

Many metals that can be formed if oxides are heated above the stability range for the corresponding p_{O_2} (Pb, Cd, Bi, Ga) can alloy with Pt and other noble metals. The T_m of such alloys are usually much lower than $T_m^{(Pt)}$. Adequate $p_{O_2} > p_{O_2}^{eq}(T)$ have to be applied in such cases.

Fig. 2 Stability regions of different metal oxides. The subsequent bars mark (from the left to the right) the stability ranges for (a) $p_{O_2} < 10^{-20}$ bar, (b) 10^{-20} bar $\leq p_{O_2} \leq 10^{-15}$ bar, (c) 10^{-15} bar $\leq p_{O_2} \leq 10^{-10}$ bar, (d) 10^{-10} bar $\leq p_{O_2} \leq 10^{-5}$ bar, (e) 10^{-5} bar $< p_{O_2} \leq 1$ bar on the T axis.

The growth of oxides with medium $T_m \lesssim 1500^\circ\text{C}$ is usually performed in conventional Cz setups using resistive or rf heating. Platinum or Pt alloys are the conventional materials for crucibles, seed holders, and other constructive parts that are in contact to the melt, as Pt is almost stable against metal oxide melts if heated under air with $p_{\text{O}_2} \cong 0.2$ bar. Bismuth germanate ($\text{Bi}_4\text{Ge}_3\text{O}_{12}$), bismuth silicate ($\text{Bi}_4\text{Si}_3\text{O}_{12}$, not treated here in detail) and the tungstate SCs from the upper part of Table 3 can be grown by this method. More problems arise upon the growth of oxide crystals with $T_m \gtrsim 1500^\circ\text{C}$ where Pt cannot be used. Iridium can substitute Pt in this higher T range; but Ir has some drawbacks compared to Pt in addition to substantial higher production costs: (1) Below $T \simeq 1200^\circ\text{C}$ Ir should only be heated in oxygen-free atmosphere ($p_{\text{O}_2} \lesssim 10^{-5}$ bar), as the formation of volatile IrO_2 destroys the metal. Even above 1200°C only $p_{\text{O}_2} \leq 10$ mbar should be used. (2) Brittleness and porosity of Ir parts are, depending on the production technology, usually considerably higher than those of Pt.

Some high melting oxides from the bottom part of Table 3 can be grown under almost oxygen-free atmosphere ($p_{\text{O}_2} \lesssim 10^{-15}$ bar) by Cz from molybdenum or tungsten crucibles. Both metals are more noble than the RE metals or Al, respectively, and less expensive than Ir. Petrosyan *et al.* (1998) reported the VBr growth of lutetium orthoaluminate (LuAP) within Mo tubes under Ar/ H_2 atmosphere ($T_m^{(\text{LuAlO}_3)} = 1900^\circ\text{C}$).

The highest-melting SCs are RE aluminates or RE silicates. The stability ranges for the RE(III) oxides (Fig. 2) are widely extended to very low p_{O_2} . Therefore, the application of fairly reductive atmospheres without reduction of the oxide to the RE metal is possible. Y_2O_3 behaves here very similar to the true rare earth metal oxides Lu_2O_3 , Gd_2O_3 , Ce_2O_3 . It should be mentioned, that even nominally ‘inert’ atmospheres as Ar are not really inert. A 5N noble gas contains 10^{-5} bar impurities that might be either oxidative (O_2) or reductive (e.g., H_2 , CO , CH_4). Accordingly, the behavior of the melt within such ‘inert’ atmospheres can be highly unpredictable. Alumina is for $p_{\text{O}_2} \geq 10^{-14}$ bar stable up to the melting points of all SCs from Table 3.

Ce_2O_3 is nearly as stable as the other RE(III) oxides under reductive atmosphere; but behaves differently under oxidizing atmosphere. Then oxidation $\text{Ce}_2\text{O}_3 \rightleftharpoons \text{CeO}_{1.72} \rightleftharpoons \text{CeO}_{1.82} \rightleftharpoons \text{CeO}_2$ takes place. At $T = 1600^\circ\text{C}$ the oxygen content at which the intermediate cerium oxides with mixed valency are stable is in the 10^{-10} bar $\lesssim p_{\text{O}_2} \lesssim 10^{-5}$ bar range and shifts upwards with T . The yellow color of some Ce doped SCs is due to the partial oxidation $\text{Ce(III)} \rightleftharpoons \text{Ce(IV)}$ and can often be bleached by annealing the crystals in suitable atmosphere.

Usually RE aluminates and silicates are grown by Cz with inductive heating. Coupling the rf heating energy directly to the crucible wall allows to obtain temperatures of up to $T_m \simeq 2200^\circ\text{C}$. Careful adjustment of the temperature gradients to values of typically $G_T \lesssim 30 \text{ K cm}^{-1}$ near the liquid/solid interface of the growing crystal and within the crystal has however to be performed. Both afterheaters and thermal insulation can reduce the high G_T that are typical for rf heated Cz growth, and avoid thermal cracking and overheating of the melt. If the heat insulation of the crucible wall is insufficient, the melt in the vicinity of the walls is strongly overheated and intensely evaporates, which can result in the change of the melt stoichiometry (cadmium tungstate, lead tungstate), in the formation of metastable phases (bismuth silicate), or in fracture of the crucible (lutetium orthosilicate, gadolinium orthosilicate, lutetium aluminum perovskite). Reiche *et al.* (1985) showed that bottom heaters can suppress the crystallization on the crucible bottom. A typical setup for the growth of high T_m oxides is shown in Fig. 3. Felt, grains, and ceramic parts are either made of alumina or, for the highest T_m , zirconia. However, the application of zirconia ceramics has to be performed with caution, as the electric conductivity of ZrO_2 rises drastically for $T \gtrsim 1000^\circ\text{C}$. Dangerous discharges can often be avoided by separating the induction coil from the zirconia ceramic with a fused silica tube.

The growth of oxides with high melting point is expensive for a number of reasons:

Fig. 3 Cz-growth setup for oxides with $T_m \gtrsim 1500^\circ\text{C}$.

- (a) The energy consumption is high.
- (b) The experimental setups (Fig. 3) are complicated and Ir (instead of Pt) has to be used.
- (c) Crucible erosion increases considerably with T .
- (d) Many RE oxides and even SiO_2 with high purity ($\geq 4\text{ N}$) are expensive.

For these reasons the mass production of such crystals (except YAG that is also used for laser applications) is restricted. Low melting point SCs, such as NaI or BGO, are nowadays the ‘working horses’ for most applications. Nevertheless, the superior properties of some modern SCs as Lu_2SiO_5 , Gd_2SiO_5 , or Y_2SiO_5 in terms of radiation hardness and thermal stability, allow to expect a growing demand for these new materials, particularly if large dimensions are not necessary.

PWO The growth of $\gtrsim 300\text{ mm}$ long boules by the Cz method employing resistive or rf heating has been reported by different authors. Quantum yield and radiation hardness depend considerably on the growth atmosphere and are found to degrade if the crystal deviates from the exact stoichiometry. Namely, point defects such as Pb^{3+} , O^- , and F centers are responsible for the slow scintillation decay component and for the afterglow. Furthermore, the tetragonal crystals exhibit a cleavage plane (001) that can cause fractures during growth or processing of the boules. The yellow color of some crystals is usually not due to impurities of the starting material but connected with excess oxygen during growth and subsequent annealing. This leads to an absorption band peaked at 430 nm.

CWO Remarkable results (crystal diameter 55 mm, length 250 mm) were reported from Kharkov, Ukraine by Bondar *et al.* (1997); but the material can be prepared in thin films as well, for the detection of α - and β -particles. Negative effects related to non-stoichiometry and impurities occur like in the case of PWO. Possible impurities are ^{232}Th and ^{226}Ra . These are especially crucial for scintillator applications and can lead to background activities of typically $10\text{ }\mu\text{Bq kg}^{-1}$.

CdWO_4 and ZnWO_4 are the only pseudo-binary compounds formed by the systems CdO (or ZnO)– WO_3 . In both cases these pseudo-binary compounds are considerably more stable against thermal decomposition and/or evaporation at elevated T than the simple metal oxides.

BGO This material can be used for scintillator applications as single crystal, as thin film and as ceramic product. Usually boules of up to 15 cm diameter are grown by Cz, but growth by VBr was reported too. The scintillation efficiency of BGO depends strongly ($\simeq 1\%\text{K}^{-1}$) on temperature.

The abbreviation BGO is used for both bismuth germanates $\text{Bi}_4\text{Ge}_3\text{O}_{12}$ and $\text{Bi}_{12}\text{GeO}_{20}$; only the former is used as SC. The growth is usually performed from Pt crucibles, but unfortunately Pt is partially solved by the melt and can form metallic inclusions within the crystal. Low thermal gradients must be used in order to avoid overheating and the loss of Bi_2O_3 by evaporation.

YAP(Ce) (=YALO), LuAP(Ce) All three binary yttrium aluminates with different stoichiometry ratio have $T_m > 1800^\circ\text{C}$. Both garnet ($\text{Y}_3\text{Al}_5\text{O}_{12}$, YAG) and perovskite are important for laser as well as for scintillator applications. Petrosyan *et al.* (1998) described growth and properties of LuAlO_3 (LuAP).

LSO(Ce), GSO(Ce), LYSO(Ce) These RE orthosilicates crystallize monoclinic. GSO shows high anisotropy of the thermal expansion and of the elastic constants. Careful adjustment of the thermal gradients and growth along the b axis were reported to reduce cleavage problems in Cz crystals. Boule dimensions can reach a diameter of 80 mm and a length of 280 mm. Crystal color as well as surface quality depend on the oxygen content in the growth atmosphere (usually N_2). $\text{Y}_2\text{SiO}_5(\text{Ce})$ can also be grown from stoichiometric melts by Cz, but some other RE orthosilicates as Ce_2SiO_5 and La_2SiO_5 were reported to melt incongruently.

These crystals combine high efficiency, short decay time, and excellent radiation hardness with high thermal stability of the scintillation properties. They SCs have mainly been established in the last decade and can be regarded as good potential materials. Unfortunately, the extremely high $T_m^{(\text{Lu}_2\text{SiO}_5)} \simeq 2150^\circ\text{C}$, that is close to the breakdown of Ir crucibles, and the high price of Lu_2O_3 restrict the availability of single crystals.

Summary

NaI(Tl) and other low melting point halide crystals are often used as SCs. They are suitable for ‘easy’ working conditions (T , p , energy of radiation). Boule diameters up to 50 cm can be obtained. Hydrolysis of the halides must be avoided to obtain high optical quality. $\text{Bi}_4\text{Ge}_3\text{O}_{12}$ or different tungstates represent alternatives. The main defects that are introduced during oxide crystal growth are connected with the maintenance of the desired valency level. RE silicates and aluminates exhibit extremely good SC properties, but due to their high T_m the growth of crystals is difficult and expensive.

Introduction

Solid-state lasers have been studied since the discovery of laser in the 1960s (Maiman, 1960), and have since found a vast range of applications from materials production industry to medicine, analytical methods, metrology or defense, with single crystals as the active medium. After the discovery of synthetic yttrium aluminum garnet (YAG, $\text{Y}_3\text{Al}_5\text{O}_{12}$) as a nearly ideal laser host and the successful laser tests of Nd:YAG at room temperature by Geusic *et al.* (1964), YAG with rare earth doping became the material of choice thanks to the narrow emission linewidth and reasonably long fluorescence lifetime. Until now YAG single crystals are still the most commonly used solid-state laser host. Although there have been successful laser tests with polycrystalline gain media already in the early years of the “laser era”: Dy:CaF₂ (Hatch *et al.*, 1964) laser under cryogenic conditions, and later in the 1970s Nd:Y₂O₃-ThO₂ (Greskovich and Chernoch, 1973), the tests remained at the laboratory level, since these materials could not compete with the optical quality of single crystals. Another important group of laser host materials are glasses. Since the focus of this chapter is on ceramic materials, neither glass nor single crystal laser materials will be discussed here, except for comparison.

Ceramic laser gain media are single-phase polycrystalline materials, mainly with cubic crystalline structure, doped with active laser ions, the transition metals or lanthanides. All laser gain media have the stringent requirement of transparency in the wavelength range of the absorption and emission range, they need to allow the incorporation of the active ion in their crystal structure, and they must have the thermal and mechanical properties to withstand the laser operation. Moreover, compared to transparent ceramic materials for other applications (phosphors, light converters, protective windows), the optical quality of laser gain media must be very high, and microstructure as pore-free as possible.

While there has been interest in the production of polycrystalline laser gain media, and of transparent ceramics in general, the optical quality of ceramics was not high enough to allow laser emission for practical use.

The first understanding of the possibility to reach transparency in ceramics probably arose from Coble's work on translucent alumina. The use of a pure powder, sintering additive and a specific controlled sintering atmosphere showed the direction that later led to the production of transparent ceramics. In 1984, de With and van Dijk (1984) and in 1990 the group of Sekita together with Yanagitani from the Konoshiba Chemical Company (Sekita *et al.*, 1990) reported on the production of translucent and transparent YAG ceramics, respectively, but the optical quality was still not sufficient for laser emission. Finally, Ikesue *et al.* (1995) presented Nd:YAG laser ceramics produced by reactive sintering of oxides under vacuum with the use of a sintering aid, and later on, 1.46 kW of output power was reported with the use of a ceramic Nd:YAG laser rod prepared from precipitated YAG powder (Lu *et al.*, 2002).

The research of transparent ceramics for laser applications has made a leap ahead in the past decades in the understanding of the conditions and processes leading to materials of high optical quality, and in the preparation and testing of new materials. Although in mass production transparent ceramics still do not replace single crystals, they already find practical applications, especially where they overperform single crystals.

The ceramic production process provides a series of advantages over the traditional single crystal melt-growth techniques:

- *Production conditions*

Production wise, while in the Czochralski crystal growth method the material has to be melted and the growth times can reach tens of days depending on the crystal size, ceramic sintering occurs at temperatures often few hundreds of °C below the melting temperature, and last from hours to tens of hours, depending on the production method.

- *Dopant concentration*

Avoiding the presence of melt, the segregation of ions in ceramics is significantly limited, allowing higher concentrations of dopant ions in the host: while the maximum concentration of Nd in Czochralski-grown YAG single crystals is 2%–2.5% (The notation used for the concentration of dopants in garnets describes the amount of doping ions which substituted the ions in the crystal lattice of the host. In the case of 1% Nd:YAG this means that one 1% of Y³⁺ ions were substituted by Nd³⁺ ions, and the chemical formula is Nd_{0.03}Y_{2.97}Al₅O₁₂), Nd:YAG ceramics were produced with Nd doping as high as 8% (Dubinskii *et al.*, 2005).

- *Shaping flexibility*

Perhaps the most important advantage of transparent ceramics is the high flexibility of the production process, particularly in terms of near-net-shaping and of the spatial control of the distribution of the doping ions. The production of single crystal components is expensive also because it requires cutting and machining from the as-grown boule to the final shape. Moreover, there are growth-induced inhomogeneities (core and facets related to the orientation of the crystal seed, variation in composition along the growth direction, segregation of doping ion), which further limit the final-part to grown-crystal volume ratio, i.e., there is a significant amount of scrap material from the production of single crystal components.

- *Spatial control of composition*

In the case of components with non-uniform dopant distribution, some geometries may be produced also from single crystals by bonding. This process, however, requires expensive high-precision polishing, and is used for planar bonded interfaces. Ceramic processing offers a number of shaping methods that allow the production of such structures in the green state, i.e., during the shaping of powders or after a light pre-sintering, providing then a composite structure with well controlled distribution of the dopant(s) without the need of additional post processing.

- *Size*

Ceramic technology also allows the production of larger components (at least in two directions) than single crystals, e.g., the large-aperture amplifiers for high-power laser research facilities, which often have an edge cladding with a different dopant (see Section Applications, beyond the state of the art.), as illustrated in Fig. 1.

On the other hand, laser-quality transparent ceramics are difficult to obtain and even a slight variation in the production process parameters can deteriorate the final performance. The main challenge in the preparation of transparent ceramics for lasers is the elimination of porosity and second phases, which has to be dealt with at every step of the fabrication process. Up to now, the reproducibility of the production of transparent ceramics is one of the factors limiting their commercial use.

Optical Transparency

Transparency of a material depends mainly on its composition and microstructure. The former is an important issue for the primary choice of the material itself. In the particular case of laser host materials, they have to be transparent in the range of wavelengths of interest (absorption, emission) in order to allow laser oscillation, i.e., the crystal host should not interfere with the

Fig. 2 Illustration of the scattering of light in optically isotropic transparent ceramics: scattering by secondary phases (1), surface roughness (2), porosity (3) and on a grain boundary (4).

passing radiation. This depends on the structure of the electron energy bands of the material; for the range from UV or visible to NIR, transparent materials are mostly oxides, halides and chalcogenides.

Theoretical transmittance of a material (when absorption is neglected) may be calculated from its refractive index, as described by Eq. (1), which considers transmission losses only due to Fresnel reflection on the two faces of the material at normal incidence. Messing's group proposed to reserve the term *transparent* for ceramics with in-line transmittance at least 95% of the theoretical value, to distinguish truly transparent ceramics from translucent ones (Kochawattana *et al.*, 2008).

$$T_{th} = \frac{2n}{n^2 + 1} \quad (1)$$

As already mentioned above, the transparency of ceramic materials is strongly affected by the microstructure, in particular by inhomogeneities acting as scattering centers.

Transparent ceramics are polycrystalline materials composed of usually randomly oriented grains in the size range from tens of nm to tens-hundreds of μm . In the case of optically anisotropic materials, viz. materials with a non-cubic crystalline structure where the refractive index varies with the orientation of the crystal, different orientation of the single grains can cause losses in direct transparency due to birefringence. Although it is possible to produce transparent ceramics with a non-cubic crystal structure, it is very difficult to achieve the optical quality suitable for laser applications. Approaches to solve this issue are discussed later.

In optically isotropic ceramics, where the issue of birefringence is not present for the wavelengths of interest (Burnett *et al.*, 2001) the scattering centers are mostly pores and second phases. Light scattering occurs on heterogeneities of the optical medium; the most typical scattering sources in a transparent ceramic material are illustrated in Fig. 2.

The presence of second phases may in most cases be prevented by a careful control of composition, use of highly pure materials and by avoiding contamination during the production process. A single-phase material is required for laser-quality transparent ceramics, since any additional phase in the system with a different refractive index will scatter light. It has to be said that, unlike single crystals technology, ceramic processing requires also a favorable powder morphology in order to obtain defect-free materials. The combination of high purity, desired particle size distribution and spherical shape is a difficulty faced by many producers and researchers in the field of transparent ceramics; often the solution lies in in-house precipitation of powders (Sanghera *et al.*, 2011a). Second phases may be also present in the form of nanometric crystallites at grain boundaries, which may appear at slow cooling rates after sintering and cause both scattering losses and decrease in laser efficiency (Ikesue *et al.*, 2006).

The presence of porosity, on the other hand, is inherent to ceramic materials, which are made by the sintering of powders. However, whereas conventional ceramics with 99.9% of the theoretical density would already be considered fully dense materials, in the case of transparent ceramics, 0.1% porosity can reduce the in-line transmittance even to zero. The effect of pores on scattering is usually higher than that of secondary phases, because the difference between refractive index of the material and the pore is larger. For practical purposes, it does not make a difference whether the pore is void or contains air or other gas introduced during the material fabrication process, as these have a significantly lower refractive index than solids, usually very close to unity.

The intensity of scattering depends on the wavelength of the incident light and on the size of the scattering center: when the two are close, the scattering intensity increases. In the visible-to-NIR range, the effect of micrometer-sized pores and defects is much higher compared to that of finer porosity. In laser ceramics the requirement of a microstructure free of scattering centers is even more stringent as scattering of light leads directly to losses in laser efficiency (defined as the ratio between the input, mostly the incident pump power or the pump power absorbed by the gain medium, and the output power of the laser), and the suggested upper limit of porosity for laser ceramics is 150 ppm (Ikesue and Yoshida, 1999).

There is an extensive amount of literature dealing with the transmittance of ceramics and the effect of microstructure (Apetz and van Bruggen, 2003; Ikesue *et al.*, 2005; Ikesue and Yoshida, 1999; Krell *et al.*, 2009a, 2014; Pabst and Hostaša, 2013; Pecharrmán *et al.*, 2009), and with the evaluation of porosity in these highly dense materials, which, unlike most ceramics, allow also the use of optical techniques (Boulesteix *et al.*, 2010; Krell *et al.*, 2014; Stuer *et al.*, 2012).

As far as the approaches to produce transparent ceramics from optically anisotropic materials are concerned, there are two main directions: reduction of grain size, or the orientation of grains.

The first possibility has been more widely studied, as it can be applied to generally any material, and most attention has been paid to transparent Al_2O_3 as a counterpart to monocrystalline sapphire. Krell *et al.* (2009b), Pecharrmán *et al.* (2009) and later

Stuer *et al.* (2012), managed to produce translucent-to-transparent alumina with submicrometric and nanometric grains. Still, the transmittances do not reach the theoretical values in the visible and NIR range, and although the obtained results are promising in the area of protective windows, the transparency is not high enough for laser materials.

It is the second option that has proved useful for the fabrication of laser gain media. The principle lies in the creation of a texture by orienting the crystalline grains in the same direction with the use of a strong magnetic field during the shaping step. This approach has been proposed by the Taira group (Akiyama *et al.*, 2011) for the production of a ceramic laser material from hexagonal (and thus optically anisotropic) neodymium-doped fluorapatite, $\text{Nd}^{3+}:\text{Ca}_{10}(\text{PO}_4)_6\text{F}_2$. In the cited work the authors apply a strong magnetic field (1.4 T) during colloidal forming step to create an oriented microstructure making use of the magnetic anisotropy of Nd^{3+} ions and densify the material by means of hot isostatic pressing. The obtained polycrystalline ceramics allowed laser operation.

The optical properties and laser performance of gain media are also affected by the presence of oxygen crystal defects like oxygen vacancies, or impurities. These latter may be present in the starting powders, introduced to the material during the production process, but also added intentionally as sintering aids, as discussed in Section Sintering aids.

Thermal Properties

After optical characteristics, thermal, thermos-optical and thermo-mechanical properties are the most important in solid-state lasers. Thermal conductivity of the active medium determines the cooling geometry of the whole laser device, because especially in high-power lasers a significant amount of heat is generated during the laser oscillations. The presence of large temperature gradients can lead to the creation of stresses in the material, surface deformation and variation in optical properties, deformation of the laser beam profile, decrease in laser efficiency, and in the worst case can lead to the fracturing of the laser medium (Cousins, 1992). For laser applications it is thus important that the material has a high thermal conductivity and low thermal expansion coefficient.

One advantage of ceramic materials is their relatively high thermal conductivity with respect to that of glasses: the thermal conductivity of glasses is usually around $1 \text{ W m}^{-1} \text{ K}^{-1}$ at room temperature, while that of ceramics can reach values about one order of magnitude higher depending on the composition and the presence of doping ions, comparable to that of single crystals. Moreover, ceramic materials have a higher shock resistance compared to their single crystalline counterparts.

Ideal transparent ceramics do not contain second phases and contain only a small amount of pores, which would decrease their thermal conductivity (although compared to the effect on optical properties, the change in thermal conductivity would be very small). For the same composition, the only difference between a ceramic and a single crystal is the polycrystalline microstructure of the former, viz. the presence of grain boundaries. Indeed, thanks to the crystalline structure and a nearly defect-free microstructure, the thermal conductivity of polycrystalline ceramics at room and at elevated temperature is identical to that of single crystals with the same composition. Grain boundaries become important at low temperatures, when the phonon mean free path approaches the same order of magnitude (Pabst and Hostaša, 2011) and phonons are scattered. A significant difference in thermal conductivity between single- and polycrystalline YAG was observed at cryogenic temperatures (Yagi *et al.*, 2007). A maximum of the thermal conductivity was observed at temperatures between 25K and 40K, with the peak value of about $800 \text{ W m}^{-1} \text{ K}^{-1}$ measured for the single crystal and $100 \text{ W m}^{-1} \text{ K}^{-1}$ for the ceramics, and there was a decreasing trend of thermal conductivity with decreasing grain size. The effect of grain size has been addressed in Bisson *et al.* (2007) and Klemens, (1993). As described by Klemens (1993), at high frequencies the strongest scattering is due to point defects, while at low frequencies it is the case of extended defects: boundaries. Another important source of phonon scattering are lattice defects represented by the dopant ions. At low temperatures, the effect of dopant and grain boundaries may be comparable (Sarhou *et al.*, 2017), but the influence of doping ions remains significant also at elevated temperatures (Hostaša *et al.*, 2019). The problem has been elaborated by Sato *et al.* (2009), and by Gaumé *et al.* (2003), who proposed a model for the prediction of the thermal conductivity of doped crystals. It can be said that while the possibility to incorporate the doping ions in the crystal lattice of the host strongly depends on the ionic radii of the substituting and substituted ions, the difference of their atomic mass is what affects the thermal conductivity. An example is the Yb doping in YAG and LuAG. While the size of Yb^{3+} , Y^{3+} and Lu^{3+} ions is comparable, the atomic mass of Y (89 g mol^{-1}) is about a half of that of the two lanthanides (173 g mol^{-1} and 175 g mol^{-1} for Yb and Lu, respectively). When 5% of Y or Lu is substituted by Yb, the thermal conductivity of YAG at room temperature drops by more than 30%, while that of LuAG remains nearly unchanged (Beil *et al.*, 2010; Hostaša *et al.*, 2019).

Thermal conductivity of the most common crystalline laser host materials at room temperature is shown in Table 1, together with other important properties. Correct selection of materials, taking into account their thermal properties, can help avoid the deterioration of laser beam quality and the decrease in the efficiency and output power deriving from thermal effects (Sanghera *et al.*, 2011a). A possibility to mitigate these effects, provided by the ceramic processing, is the production of materials with engineered doping distribution (Esposito *et al.*, 2014).

Processing Technologies

Transparent ceramics may be prepared by a wide range of methods offered by the ceramic technology. However, the production of laser-quality transparent ceramics requires a precise control of every step of the process in order to avoid the formation of defects.

Table 1 Laser host materials and their properties at room temperature; the presented data were measured either on ceramics or single crystals, as the difference is usually very small and not all are available for ceramic materials; an intermediate value or a data range is presented in the case of multiple values of a comparable relevance for a given material and property

Material	Thermal conductivity at room temperature ($W m^{-1} K^{-1}$)	Transparency range (μm) ^a	Thermal expansion coefficient ($\times 10^{-6} K^{-1}$)	Thermo-optic coefficient dn/dt ($\times 10^{-6} K^{-1}$)	Density ($g cm^{-3}$)	Melting temperature ($^{\circ}C$)
YAG	10.7	0.23–6.4	6.1	7.8–8.4	4.56	1940
LuAG	8	0.23–6.3	6.1	4.9–8.3	6.67	2060
Sc ₂ O ₃	16.5	0.23–6.7	6.4	8.12	3.86	2430
Lu ₂ O ₃	11.4	0.23–7.7	6.1	7.1	9.42	2444
Y ₂ O ₃	13.0	0.25–9.6	6.3	6.08	5.04	2430
CaF ₂	10	0.13–12	19.2	–12.7	3.18	1420
MgAl ₂ O ₄	19–24	0.19–6.0	5.9	9–14	3.58	2135

^aThe transparency range is approximate, with the IR transmittance cutoff corresponding to values from 0% to 50% of transmittance, depending on the source of data.

Note: Data from (Beil *et al.*, 2010; Brown *et al.*, 2016; Furuse *et al.*, 2014; Goldstein and Krell, 2016; Harris *et al.*, 2013; Hostaša *et al.*, 2019; Kong *et al.*, 2015; Le Garrec *et al.*, 2013; Nigara, 1968; Rubat du Merac *et al.*, 2013; Sanghera *et al.*, 2012; Sarthou *et al.*, 2017; Slack, 1962; Wang *et al.*, 2013).

The purity and morphology requirements of the starting powders are pivotal. Often, nanometric and sub-micrometric powders provide the best results, as long as they are only loosely agglomerated. The shaping process needs to provide a uniform green body without variations in density or composition, and free from voids, bubbles or other inhomogeneities. The creation of large defects or cracks could also arise from the thermal removal of water, organic additives or other compounds, sometimes added during the shaping step, from which gas is released or which evaporate with the increase of temperature. The full densification is then obtained by sintering, often under vacuum or pure gas atmosphere, by the application of external pressure, or by a combination of these methods.

The aim of this section is to illustrate the most commonly used approaches and possibilities and to point out the important issues and parameters that are encountered in the production of transparent ceramics for laser applications.

Powders

The availability of fine, highly pure powders has been increasing in the past decades, giving more possibilities also for the production of transparent ceramics from commercially available starting materials. Nevertheless, the requirements of transparent ceramics for laser applications are very high, and especially in the research area, laboratory-synthesized powders are often preferred (Sanghera *et al.*, 2011a).

Most of the production processes involve the use of submicrometric or nanometric powders because of their high specific surface area and the high reactivity, possibly composed of spherical particles, which can be readily packed into dense structures. The decrease of particle size also leads to the increase of surface curvature, supporting thus further densification (Cannon and Carter, 1989; Fang and Wang, 2010).

However, the right shape and size of the particles is not enough. Agglomeration, and above all the presence of hard agglomerates in the powders during the shaping process can introduce inhomogeneities and voids in the microstructure, which cannot be removed at later stages of the production process (Sanghera *et al.*, 2011b). Of course, both the particle size and presence of hard agglomerates may be controlled by a milling step, yet considering the possible contamination from milling media and container.

Two different approaches can be followed for the production of transparent ceramics, as already mentioned in Section “Optical Transparency” for the case of YAG:

- sintering of synthesized powders with the desired composition (Lu *et al.*, 2001; Sanghera *et al.*, 2011a),
- solid-state reaction sintering of a mixture of the constituent oxide powders (Bonnet *et al.*, 2018; Ikesue *et al.*, 1995; Lee *et al.*, 2006).

The synthesis of powders provides a better control over the powder characteristics and very high chemical homogeneity, whereas the solid-state reaction offers a major flexibility for the preparation of new batches and an easier scaling up. Synthesized powders are more suitable for certain shaping methods, e.g., casting, and for fast sintering processes like SPS, where the process speed would be limited by the no need for a solid-state reaction to occur.

There are numerous methods used for the synthesis of powders, among which the most important ones are precipitation ((Kim *et al.*, 2015; Li *et al.*, 2000), used also by the Konoshima company (Yagi *et al.*, 2007)) and thermal decomposition (e.g., flame spray pyrolysis (Jones *et al.*, 2018)).

A crucial step in the case of precipitation is the thermal treatment – calcination of powders, during which the precursor crystallizes. The choice of the proper calcination temperature is very important, since too low temperatures would not lead to the

formation of the desired phase, which could cause problems during sintering, while too high temperature would lead to the coarsening of the particles, formation of necks and even hard agglomerates, which would be difficult to disintegrate.

The reactive sintering is attractive especially in research, where the process flexibility and possibility to prepare batches of arbitrary size is much appreciated especially in the case of garnet ceramics, a lot of effort has been made to understand the reaction mechanisms and the roles of sintering aids and dopants (Boulesteix *et al.*, 2009; Hostaša *et al.*, 2012; Stevenson *et al.*, 2011b). For YAG, the reactive sintering model has been described by Ikesue *et al.* (2013) and Kupp *et al.* (2014), discussing also the effect of the particle size of Y_2O_3 and Al_2O_3 . The respective chemical reactions are shown below, in Section YAG. The preparation process is less complex than precipitation of YAG powders; however, the importance of the characteristics of starting powders is crucial.

As a general rule, there is a difference in the microstructure between the ceramics produced from the synthesized powders and those obtained by solid-state reaction sintering: although it is strongly dependent on the sintering process, the typical grain size of solid-state sintered materials may be about one order of magnitude larger (e.g., in YAG tens of microns compared to few microns in ceramics produced from a precipitated powder).

Under all processing conditions it is critical to maintain the correct stoichiometry of the powder, mainly to avoid the formation of second phases (e.g., in YAG).

Shaping

The most common shaping methods in transparent ceramics production are dry pressing, slip casting and tape casting. Pressing has been used for its simplicity, and provides good results for simple geometries. Slip casting has proved particularly useful for the production of highly uniform green bodies and unconventional shapes. The advantage of tape casting lies in the ease of the preparation of planar materials with structured dopant distribution. Recently, good results were obtained also with the use of gel casting of Nd:YAG (Jing *et al.*, 2018), a method more commonly used for the shaping of transparent spinel, and extrusion was used to produce polycrystalline YAG fibers with diameter below 30 μm (Kim *et al.*, 2017). Finally, a fully transparent YAG ceramics with co-axial Nd^{3+} distribution was prepared by additive manufacturing process (Jones *et al.*, 2018).

Dry pressing, granulation

The powder is compacted by the application of pressure; uniaxial in a die, isostatic with the application of pressure through a liquid, or a combination of both. The use of cold isostatic pressing has proved very useful for the increasing of the density of the pressed compact before sintering, providing a better packing of the powder particles and leading to increased transparency.

To obtain uniform green body by pressing it is important that the powders flow well and do not contain hard agglomerates. Unfortunately, that is often not the case for fine particles, which tend to be voluminous and are difficult to press. An efficient way to increase the flowability of a powder, and consequently the packing density of a dry-pressed green body, is the granulation of powders before pressing.

Granulation of powders for transparent ceramics is usually performed by spray drying or freeze drying of suspensions: suspension droplets are fixed either by the evaporation or freezing and subsequent sublimation of the dispersing phase. When pressed, the granulated powders can be rearranged more easily to remove voids and provide a more uniform compact. Ikesue *et al.* illustrated the effect of the change in one parameter of the spray drying process on the final porosity of transparent YAG ceramics (Ikesue and Yoshida, 1999).

The role of granulation is even more important in the case of powder mixtures, where the desired composition is maintained within the granules, preventing particles with different size or density from separation and maintaining homogeneity.

Slip casting

Slip casting is another traditional ceramic shaping method. To obtain transparent ceramics, the slurry has to be free of bubbles and agglomerates, and should have a high solid loading; Appiagyei *et al.* (2008) found that the best results were obtained with well-dispersed Newtonian suspensions. Slip casting has been successfully employed by the Konoshima company with the use of precipitated YAG powders (Yagi *et al.*, 2007), while the group of Boulesteix used slip casting to produce transparent garnet ceramics by reaction sintering (Bonnet *et al.*, 2015).

While usually gypsum molds are used for slip casting, the contamination risks in transparent ceramics technology require porous materials that do not release any impurities in the green body, and thus sometimes the material of choice is porous alumina (Ivanov *et al.*, 2016).

A variation of the slip casting method, pressure casting, or pressure-assisted slip casting also provided good results (Kopylov *et al.*, 2009), and an illustration of pressure-cast Nd:YAG ceramics made via reactive sintering by the group of Boulesteix is shown in Fig. 3.

Tape casting

Tape casting is a method born for the production of thin ceramic sheets. A suspension is prepared with a high content of organic binder and dispersant, which is cast in the form of a thin foil (tape) of a typical thickness about 100 μm (Messing *et al.*, 2009), that is elastic due to the high content of organic additives and can be easily manipulated. To obtain a bulk piece, the tape sheets can be stacked and compressed together at slightly elevated temperature (usually not above 100°C), when the organic binders soften

Fig. 3 Nd:YAG ceramic components produced by pressure casting at 3 MPa of an aqueous suspension of $\text{Y}_2\text{O}_3\text{-Al}_2\text{O}_3\text{-Nd}_2\text{O}_3$ powder mixture; (a) pressure-cast green body, (b) sintered disks, (c) a rod composed of layers of Nd:YAG and layers of dopant-free YAG. Courtesy Dr. Boulesteix, Univ. Limoges, joint laboratory IRCER/CILAS.

(Mistler and Twinaime, 2000). Due to the high content of organic additives, a particular attention has to be paid during the debinding (burnout) heat treatment, which is a necessary step before sintering, so that all the organics are removed, but no damage is caused to the green body from the released gases.

Tape casting is particularly useful for the production of bulk layered, planar-shaped ceramics, because it provides a high-precision control over dopant distribution in the sintered component and low concentration of defects. Although diffusion between the layers cannot be avoided during the sintering, the thickness of the dopant diffusion gradient profile is in the range of 100 μm (Hostaša *et al.*, 2016; Kupp *et al.*, 2010), depending on the sintering process.

The possibilities of tape casting of transparent YAG laser ceramics have been extensively studied in the past decade (Hostaša *et al.*, 2017; Kupp *et al.*, 2010; Tang *et al.*, 2012). This technique is very well suited for the production of planar laser waveguides (Ge *et al.*, 2014; Jiang *et al.*, 2019; Ma *et al.*, 2016), where the guiding structure is made by a thin layer (tens to hundreds of μm thickness) of a doped laser gain medium confined between two parts with a different refractive index, often the dopant-free host material, which has very similar thermomechanical behavior as the gain medium.

Densification Methods

Although high densities can be achieved by conventional sintering in air under atmospheric pressure, this method does not provide a sufficient driving force for the full closure of pores necessary to produce transparent ceramics. Therefore, high-performance sintering methods need to be applied, often accompanied by the addition of a sintering aid. The most common methods are vacuum sintering, sintering in a gas atmosphere (e.g., hydrogen, oxygen) and pressure assisted sintering, viz. hot pressing (HP), hot isostatic pressing (HIP) and spark plasma sintering (SPS, also called Electric current assisted sintering, ECAS). A concise review on the densification methods of transparent ceramics was presented by Wang *et al.* (2013).

Vacuum sintering

Vacuum sintering has been successfully used for the production of different kinds of laser ceramics, including YAG, Y_2O_3 , Sc_2O_3 , Lu_2O_3 (Ikessue *et al.*, 1995; Wang *et al.*, 2013). The application of vacuum before and during sintering helps with the removal of pores by both degassing, reducing the amount of gas in the material from the very beginning, and by providing an additional force that helps the densification. The closing of pores under vacuum is beneficial to the densification process, owing to a lower amount of gas that has to diffuse from the pore, and by facilitating the evaporation – condensation process inside pores. As a result, the risk of pore entrapment inside grains is also lower. Vacuum sintering is further useful by providing a clean atmosphere, especially in the case of vacuum furnaces with refractory metal (W or Mo) hot zone shielding and heating elements.

The sintering temperatures are usually few hundred of °C below the melting temperature and sintering times usually range from hours to tens of hours. Often, small amounts of sintering aids are used to decrease the sintering temperature, promote pore closure and control grain growth.

The high vacuum acts as a reducing atmosphere, removing oxygen from the crystal structure of oxides. The as-sintered materials then often have to be annealed in air or oxygen atmosphere. In Yb-doped laser ceramics, where the presence of Yb^{3+} only is required, the annealing serves both to eliminate oxygen vacancies and to oxidize Yb^{2+} ions.

Vacuum-sintered ceramics usually have large grains (tens of μm), which limit their thermo-mechanical performance.

Two-step sintering was proposed to limit grain size by separating the grain growth from the densification process. The material is heated to a higher temperature and quickly cooled down to a slightly lower soaking temperature (the difference is usually about 100–200°C), high enough to promote grain boundary diffusion, but not grain growth, and the soaking time ranges from hours to tens of hours. The resulting microstructure is fine-grained with pores mostly at grain boundaries. Such microstructure is also well-fit for a post-HIP treatment, which eliminates the remaining porosity. This approach was successfully used to obtain transparent Sc_2O_3 and Lu_2O_3 ceramics (Serivalsatit and Ballato, 2010; Serivalsatit *et al.*, 2013).

Pressure-assisted sintering

As was listed above, the main three pressure-assisted sintering techniques applied for the production of transparent ceramics are HP, HIP and SPS.

Hot pressing uses a uniaxial application of pressure on a compact placed in a heated die to enhance densification through the rearrangement and deformation of particles. The use of hot pressing only can lead to transparent ceramics, but to achieve laser-quality materials, it is coupled with a post-HIP treatment (Sanghera *et al.*, 2011a).

Spark plasma sintering is similar to hot pressing, viz. the powder or pre-formed piece is placed in a die and is uniaxially pressed while heated. The difference is in the application of electric current in SPS, which passes through the die and the sample and heats by the Joule effect. During the SPS of transparent ceramics, electrically isolating materials, the heating occurs mainly from the die. SPS can be used to sinter nanometric powders without or only with a reduced amount of sintering aids, and compared to other methods, it is very fast (the whole treatment including the cooling is a matter of tens of minutes up to hours), providing high densification and fine-grained microstructure with very small pores, also thanks to the relatively lower temperatures. SPS has been successfully applied in the sintering of sesquioxides, providing good results without the necessity of a post-HIP treatment (An *et al.*, 2014; Boulesteix *et al.*, 2014). A comprehensive summary on the application of SPS for the production of transparent ceramics is provided in Nečina and Pabst (2018).

In the case of hot pressing (HP) and spark plasma sintering (SPS) the forming can take place directly inside the furnace in the mold where the sample is pressed during the firing (Boulesteix *et al.*, 2014). This approach may easily lead to the introduction of impurities (mainly carbon) and does not necessarily provide a uniform compact (also due to the powder characteristics, cf. Section “Sesquioxides”), and therefore the shaping inside the SPS die is not advised for the fabrication of laser ceramics.

Hot isostatic pressing, unlike HP or SPS, uses mostly gas to apply pressure on the sintered ceramics placed in a heated chamber, and thus presents no limitation to the number or shape of the objects except for the dimension of the chamber. HIP is often applied to increase the density of samples that have been previously sintered up to the so-called closed porosity density (95%–99% of the theoretical density). The ideal microstructure of materials to undergo post-HIP treatment is composed of small grains with pores localized at grain boundaries. As was noted above, such microstructures may be achieved by the use of two-step sintering, or by HP or SPS.

Pressure-assisted sintering methods, in particular SPS and HIP, usually produce microstructures with smaller grain size, e.g., compared to vacuum sintering. This is achieved thanks to the lower sintering temperatures and shorter times allowed by the application of pressure.

Other sintering approaches

Pressureless sintering in air usually doesn't provide sufficiently dense ceramics, and with the exception of CaF_2 , discussed later in Section CaF_2 , it has to be followed by a HIP treatment (Wang *et al.*, 2016). The use of oxygen or hydrogen atmosphere gave good results in the sintering of Y_2O_3 (Zhang *et al.*, 2009) or LuAG (Zhou *et al.*, 2017). Oxygen atmosphere is also useful in pre-sintering calcination or post-sintering annealing treatments.

Hot forming is an unusual method – from the point of view of ceramic technology – used for the preparation of fluoride ceramics, where bulk singles are exposed to high pressure at elevated temperature (as in HP) and, basically, the single crystal is deformed to such extent that its structure breaks and turns to polycrystalline (Akchurin *et al.*, 2013). The idea behind hot forming is to eliminate optical inhomogeneities present in the single crystals. Although the obtained materials are pore-free, they are not fully isotropic due to the uniaxial application of pressure, and the whole process including the growth of the crystal is long and demanding.

Sintering aids

The use of sintering additives appeared to be a necessity for the production of high-quality transparent ceramics. The most commonly used are SiO_2 (sometimes added in the form of an organic precursor, TEOS), MgO , CaO , ZrO_2 ; in the case of HP and SPS processes, it is mostly LiF . Sintering aids promote densification and control grain growth, but they also introduce impurities, which may negatively affect the laser performance, as was shown for silicon (Gaumé *et al.*, 2012). The decrease of the amount of

sintering aids in YAG while maintaining the optical quality has been successfully pursued by the Messing group (Lee *et al.*, 2009; Stevenson *et al.*, 2011a), and recently Ikesue and Aung presented the synthesis of Yb:YAG ceramics by vacuum sintering followed by HIP without any sintering aid (Ikesue and Aung, 2017), which is a significant accomplishment. The production of laser sesquioxide ceramics without sintering aids by a combination of sintering under vacuum or in air followed by HIP has also been reported (Toci *et al.*, 2020; Wang *et al.*, 2016), as well as by SPS (Boulesteix *et al.*, 2014).

Materials

A major part of this section presents materials for ceramic laser gain media and details on their production and performance, and part is dedicated to other transparent ceramics used in lasers. An overview of material properties of the discussed laser hosts is presented in Table 1.

The most commonly used ceramic laser hosts are oxides, mainly rare earth garnets and cubic sesquioxides, and fluorides, in particular CaF_2 . The active luminescent ions are lanthanides and transition metals, which enter the crystal lattice of the host by substitution. The selection of a suitable host–dopant combination thus depends on the capacity of the host to accommodate the active ion in the crystal lattice. The advantage of rare-earth garnets and sesquioxides is the similar size of Y^{3+} , Sc^{3+} and the lanthanide ions. The most commonly used dopants are Nd^{3+} and Yb^{3+} for emission around 1 μm , Er^{3+} for emission around 1.5–1.6 μm and 3 μm , and Tm^{3+} and Ho^{3+} with emission in the 2 μm region. Nd^{3+} doping has been of strongest interest for decades; however, with the availability of efficient laser diodes, the use of Yb^{3+} is on the rise, in particular for high-power lasers (Paul David *et al.*, 2018).

For more information about the crystalline structure of laser hosts, dopants and spectroscopic characterization, the kind reader is suggested to look into the following publications: (Ikesue *et al.*, 2013; Koechner, 2006).

Garnets

Thanks to their optical, thermal and mechanical properties, synthetic rare-earth garnet single crystals with rare-earth doping have been the material of choice for solid-state lasers, and thanks to the success in obtaining YAG laser ceramics in the 1990s (Ikesue *et al.*, 1995; Lu *et al.*, 2000), the polycrystalline garnets have been considered a promising alternative to single crystals, and have been studied significantly up to now. These materials have the chemical formula $\text{A}_3\text{B}_2\text{C}_3\text{O}_{12}$ and a cubic structure (group Ia3d), where rare earth dopants occupy the dodecahedral A site.

YAG

YAG is most important transparent ceramic material for laser applications. A significant amount of research effort has been dedicated to the preparation and study of first Nd:YAG, and later Yb:YAG transparent ceramics for laser applications in the last two decades, bringing many interesting and important results.

As described in Section “Sintering aids”, YAG ceramics are produced either by the sintering of YAG powders, or by a reactive sintering of the single constituent oxide powders. In the latter case, the reactions occur at temperatures above 1000°C with two intermediate phases – monoclinic $\text{Y}_4\text{Al}_2\text{O}_9$, denoted YAM, and a perovskite YAlO_3 phase referred to as YAP, which has two polymorphs: orthorhombic and hexagonal. The latter is sometimes also referred to as YAH. The formation of the phases is described by the following equations:

The YAG phase is a nearly linear compound, and the deviations of stoichiometry may cause the presence of either Al_2O_3 or YAP phase in the sintered material.

As a general rule, the microstructure of YAG ceramics produced by the reactive sintering of the constituent oxide powders is coarser compared to that made from fine synthesized YAG powders. The exact grain size then depends on the sintering conditions. Transparent YAG ceramics are mostly sintered under vacuum at 1700–1800°C, usually with the use of silica as a sintering aid, both in the case of YAG powders and reactive sintering (Ikesue *et al.*, 1995; Sekita *et al.*, 1990). The use of CaO and MgO, or a combination of the two or with SiO_2 has also proved useful. MgO is particularly useful for the control of grain size (Yang *et al.*, 2012). The typical doping ions in YAG for lasers are Nd^{3+} , Yb^{3+} and Er^{3+} .

Materials of optical quality comparable to single crystals have already been produced, and thanks to the shaping techniques of ceramics, the performance and possibilities of single crystal technology have already been surpassed, e.g., by the large-aperture slabs produced by the Konoshima company (see Fig. 1). Nevertheless, so far the commercialization of transparent YAG ceramics has still been limited.

At laboratory scale, Nd:YAG gain media in the shape of a 120 × 50 × 3 mm slab (Chen *et al.*, 2014) or disk 80 mm in diameter and 6 mm thick (Ikesue *et al.*, 2006) produced by dry pressing and vacuum sintering, or Er:YAG rod 3 mm in diameter and 62 mm long with structured doping prepared by tape casting (Ter-Gabrielyan *et al.*, 2010) were reported.

Nd:YAG ceramics may be prepared with much higher Nd concentrations compared to single crystals, which allowed to obtain increased laser efficiencies (Dubinskii *et al.*, 2005; Ikesue *et al.*, 1996). High dopant concentration has also been successfully applied for Yb:YAG, reaching 10%–20% in the thin-disk or microchip lasers (Dong *et al.*, 2007). The interest in Yb:YAG arises from the possibility to construct compact lasers with the use of laser diodes. Conversely, the use of a mixed co-doping Nd,Cr in YAG allows solar-pumping of the laser through the absorption of Cr^{3+} and the energy transfer from Cr^{3+} to Nd^{3+} ions (Suzuki *et al.*, 2019).

LuAG

LuAG, $\text{Lu}_3\text{Al}_5\text{O}_{12}$, is a very interesting alternative to YAG thanks to its good thermal properties, viz. for the very low effect of rare-earth doping on its thermal conductivity (see Section “Processing Technologies”) and the availability to easily accommodate lanthanides. A lower influence of the thermo-optical effects (thermal lens) was reported for Yb:LuAG compared to Yb-doped YAG, Sc_2O_3 and Lu_2O_3 (Pirri *et al.*, 2014). Thanks to its similarity to YAG, also in-situ production of YAG-LuAG composite structures is possible, e.g., for waveguides (see Section Tape casting).

Like YAG, LuAG is mostly sintered under vacuum, often by reactive sintering of oxide powders (Xu *et al.*, 2012). Recently, the production of 0.8% Nd:LuAG slabs $58 \times 40 \times 5.5$ mm and $52 \times 39 \times 7.5$ mm by solid-state sintering under vacuum followed by HIP was reported (Liu *et al.*, 2019).

Other garnets

Other rare-earth-doped synthetic garnets have also been tested as laser gain media ($\text{Gd}_3\text{Ga}_5\text{O}_{12}$, GGG;), and there has been an interest in the use of mixed garnets (e.g., YSAG, $\text{Y}_3\text{Sc}_x\text{Al}_{5-x}\text{O}_{12}$) for the possibility to tune the absorption and emission bands and enhance the emission by the variation of the crystalline structure of the host (Feng *et al.*, 2005). Flashlamp-pumped Cr,Nd:GSGG ($\text{Gd}_3\text{Sc}_2\text{Ga}_3\text{O}_{12}$) is another promising laser material (Koechner, 2006).

Sesquioxides

Sesquioxides have the chemical formula M_2O_3 , where M is a metal, usually Y, Sc, Lu, or La, offering an easy substitution sites for lanthanide lasing ions. These materials have a cubic structure (group Ia3), high melting temperatures (above 2400°C) and are often difficult to grow as single crystals. There is a particular interest in sesquioxide laser gain media given their thermal conductivity; both pure Sc_2O_3 and Y_2O_3 have high thermal conductivity; however, due to the low mass of Y and Sc compared to lanthanides it drops with the addition of the dopant, especially in the case of Yb doping, which requires higher concentrations. Conversely, Lu_2O_3 , as in the case of LuAG, maintains its conductivity with increasing doping. Moreover, the laser emission efficiency can be significantly improved at cryogenic temperatures.

Y_2O_3 has already long been proposed as a promising laser gain medium, however its production in sufficiently high quality and dimensions was not so immediate. There is a strong limitation to the possible growth of Y_2O_3 single crystals due to its high melting temperature and to a phase transformation taking place at around 2325°C. Pure Y_2O_3 has a relatively high thermal conductivity, although decreasing significantly with the introduction of lanthanide doping ions, and a wide transparency range.

First successful attempts to produce transparent polycrystalline Y_2O_3 used a significant amount of additives (ThO_2 , or later La_2O_3 , (Greskovich and Chernoch, 1973; Ivanov *et al.*, 2016)). Recently, high-quality 5% Yb: Y_2O_3 ceramics have been prepared by vacuum sintering of precipitated nanoparticles (1700°C for 2 h) followed by HIP (1775°C for 4 h at 198 MPa), with the use of a small amount of ZrO_2 , reaching 10.6% slope efficiency (Wang *et al.*, 2017). Laser-grade 2% Yb: Y_2O_3 ceramics were prepared by Sanghera *et al.* (2011a) by hot pressing of precipitated powders with a small amount of LiF, and a slope efficiency reaching 45% was obtained both in continuous wave and pulsed mode. Slope efficiency of 48% was reported for cryogenically cooled 0.5% Er: Y_2O_3 ($20.7 \times 2 \times 5$ mm), but no details on the material production were provided (Ter-Gabrielyan *et al.*, 2008).

Sc_2O_3 is very similar to yttrium oxide in terms of material properties, and it is a candidate material for diode-pumped lasers. Transparent Sc_2O_3 ceramics have been prepared mostly from nanopowders, by vacuum sintering (Dai *et al.*, 2018; Lu *et al.*, 2003) or by combination the of vacuum sintering and HIP (Serivalsatit and Ballato, 2010; Toci *et al.*, 2020).

Lu_2O_3 has a slightly lower thermal conductivity compared to the two previously mentioned oxides; however, as noted above, it does not decrease with the addition of dopant. This makes Lu_2O_3 interesting for high dopant concentrations, useful mostly for Yb. While most of the works report on the production by vacuum sintering of nanometric powders, pressure-assisted methods have also provided very good results. Sanghera *et al.* (2011b) reported on the production of Yb: Lu_2O_3 by hot pressing (followed by HIP). The produced materials reached a laser slope efficiency of 74% and 16 W output power. More recently, the production of Nd: Lu_2O_3 via SPS has been reported both with (An *et al.*, 2014) and without the use of a sintering aid (Boulesteix *et al.*, 2014).

As in the case of mixed garnets, it is possible to tune the spectroscopic properties by mixing the sesquioxide composition thanks to their miscibility. Moreover, while the addition of La_2O_3 to Y_2O_3 is sometimes in the literature addressed as the use of a sintering aid, the quantity involved (e.g., at 10%) suggests that the final material is a mixed sesquioxide, which is easier to sinter compared to pure yttria. Laser efficiency of 17.5% was reported for 8% Yb($\text{La}_x\text{Y}_{1-x}$) $_2\text{O}_3$ ceramics prepared by vacuum sintering of nanopowders (Ivanov *et al.*, 2015) at only 1650°C for 20 h.

CaF₂

Among fluorides, the main material of choice for lasers is CaF₂ doped with rare earth ions, in particular with ytterbium. Yb:CaF₂ has been proposed, together with Yb:YAG, as one of the possible gain media for the ambitious European project HiPER – High Power laser Energy Research focused on laser-driven inertial fusion, albeit more likely in the form of a single crystal (Chanteloup *et al.*, 2010).

As mentioned above in Section “Other sintering approaches”, one approach used for the production of transparent CaF₂ ceramics is hot forming, hot pressing of single crystals, a relatively time-consuming process. The production of transparent CaF₂ by the more classical ceramic approaches have not provided impressive results until the recent work of Mortier's group, using pressureless sintering of Yb:CaF₂ nanopowders prepared by a soft chemistry process (Gredin and Mortier, 2016, Sarthou *et al.*, 2016).

MgAl₂O₄

MgAl₂O₄ spinel is a material of choice mainly for transparent windows and domes for aggressive environments thanks to its very good mechanical properties and resistance. It is produced from widely available and relatively inexpensive materials, MgO and Al₂O₃, and is already produced in large dimensions, mainly by hot pressing or by pressureless sintering in air followed by HIP. Attempts have been made to employ spinel with Cr, Mn, Ti, or Ni doping as a laser gain medium (single crystals grown by the micro-pulling-down (Jouini *et al.*, 2007a,b)), however its main use in laser technology is elsewhere. When doped with Co²⁺, spinel can be used as a saturable absorber for passive Q-switching in the wavelength range around 1.5 μm. Sanghera *et al.* also prepared highly transparent spinel for laser exit window aperture (Sanghera *et al.*, 2011a).

Non-Gain-Media Ceramics for Lasers

Apart from laser gain media, transparent ceramics are promising candidates also for other laser components, in particular absorbers and magneto-optical materials.

Absorbers

Absorbing ceramic components in lasers can be divided in two categories:

- absorbing cladding to suppress undesired amplified spontaneous emission (ASE),
- saturable absorbers.

Absorbing cladding may be realized by different approaches (principally a light absorbing, liquid or solid with a refractive index matching the laser gain medium) and it serves to absorb amplified spontaneous emission (ASE) and internal reflections of parasitic oscillations, which would limit the laser performance. It is particularly important in high-energy lasers, where the losses would create also problems with thermal management and laser beam profile. The solution for bulk laser gain media (slabs, disks) offered by the ceramic technology is production of composite structures, where the host material is doped with lasing ion (Yb³⁺, Nd³⁺) in the core and with absorbing doping (Cr⁴⁺ or Sm³⁺) in the cladding, sintered in one piece without the need of further bonding or depositions (Paul David *et al.*, 2018).

Saturable absorbers are absorbing optical components whose transmittance increases when the light intensity reaches a threshold. The main use of saturable absorbers is in passive Q-switching, a method for the generation of short pulses, often of high energy and with high repetition rate, by the change in the level of losses in the laser resonator. The materials of choice are often Cr⁴⁺:YAG for the 1 μm region, V³⁺:YAG for 1.3 μm and Co²⁺:MgAl₂O₄ for the 1.5 μm region. As in the case of absorbing cladding, ceramic technology allows the production of passively Q-switched laser in one piece, e.g., Nd:YAG/Cr:YAG (Taira, 2011; Tsunekane *et al.*, 2010).

Magneto-optical materials

Another type of transparent ceramic materials of recent interest are magneto-optical materials, that is Faraday rotators characterized by a high Verdet constant, changing the polarization of the light beam passing through the material by the application of a magnetic field. These materials have been produced mainly as single crystals of terbium gallium garnet (TGG, Tb₃Ga₅O₁₂), with the limitation of size to 30–40 mm. Another promising material, terbium aluminum garnet (TAG, Tb₃Al₅O₁₂), is difficult to produce as a single crystal due to incongruent melting. This clearly leaves a lot of space for the development of ceramic solutions, especially for the production of large-aperture components. First TGG transparent ceramics are already commercially available, with Verdet constant equivalent to that of a single crystal, and other materials, e.g., (Tb_{0.6}Y_{0.4})₃Al₅O₁₂ (Aung and Ikesue, 2017; Wan *et al.*, 2019) or ceramic yttrium iron garnet, YIG (Ikesue and Aung, 2018) are under investigation with promising results.

Applications, Beyond the State of the Art

Probably the main advantage of transparent ceramic technology lies in the shaping possibilities, in particular to produce composite or gradient structures without the need of post-processing and bonding. This was illustrated by a number of examples above, viz. composite ceramics for Q-switched lasers, cladding or waveguides. Planar waveguide lasers use the difference in refractive index between the thin layer of the laser medium and the two adjacent parts of the sandwich-like structure. The difference in refractive index may be caused simply by the laser doping ion (Jiang *et al.*, 2019) or by the use of another host, as in the case of YAG-Yb:LuAG-YAG structure (Ma *et al.*, 2016).

The shaping methods offer approaches for the shaping of materials with different geometries (slab, disk, thin disk, fiber) and dimensions. Recent advancements show that while for certain applications it is necessary to produce large gain media, miniaturization is also very interesting. The production of thin disk microchip lasers (composite thin disk with waveguides), where the gain medium is only hundreds of micrometers thick, has been proposed by Taira (2007). Eventually, the microchip lasers using ceramic YAG components were successfully tested in spark plugs for car industry (Tsunekane *et al.*, 2010), and a more recent work presented an elaborate Q-switched laser Nd:YAG/Sm:YAG microchip coupled with a Cr^{4+} :YAG part (Kong *et al.*, 2015).

Bonding still has its place, for the combination of materials with significantly different properties or production processes, e.g., with the recent possibilities of room temperature bonding (Kausas *et al.*, 2017) it would be possible to get the best both of ceramic and single crystal technology. The coupling of ceramics with single crystals has already been successfully used in 2005 (Yagi *et al.*, 2005). Bonding solutions are also useful when a minimum thickness of the interdiffusion is required. While in the case of composite structures prepared by pressing or tape casting the interdiffusion layer may be even 200 μm thick (Hostaša *et al.*, 2016), recently, Ikesue *et al.* (2018) presented a bonding method providing composites with a very clear defect-free interface. The same group also presented an approach for the growth of single crystals from transparent ceramics, which would provide materials without grain boundaries and without the optical defects typical for melt-grown single crystals (Ikesue *et al.*, 2013).

The application potential of laser ceramics is significant, covering the whole field currently using the single crystalline counterparts and beyond, and providing the advantage of a more economical use of strategic materials such as rare earth oxides. Yet, their real use is still strongly limited, partly because of low competition and relatively high prices. With a higher availability of ceramic laser gain media, there should be no obstacles in their use e.g., in diode-pumped lasers both for pulsed and continuous wave operation. Meanwhile, the ongoing research in the field of transparent ceramics keeps presenting novel materials and technological solutions and increasing quality.

Currently, there is a lot of interest in very-high-power lasers in the fields of defense and experimental physics, where large-aperture gain media are required. In terms of laser output, the Lawrence Livermore National Labs (LLNL) reported the first achievement of 67 kW and 100 kW continuous wave was achieved by a number of producers of direct energy weapons, using diode arrays and multiple large Nd:YAG or Yb:YAG slabs produced by the Konoshiba company (Sanghera *et al.*, 2013). While LLNL laser uses Nd:YAG slabs, Yb:YAG gain media have been installed in a number of high-power laser facilities, viz. GENBU in Japan; DiPOLE in the UK; HILASE in the Czech Republic, or Lucia laser chain at LULI, France (Paul David *et al.*, 2018).

Introduction

Gas sensors based on oxide materials are an established technology in safety applications, i.e., the detection of toxic or flammable gases, as well as environmental monitoring or process control. Their small size, cost-efficient production and low power consumption are advantages compared to analytical instrumentation, which on the one hand has often a higher accuracy and large application range, but on the other hand is rather large and expensive. With the fast-growing need for monitoring process or environmental parameters, the demand for suitable sensors is increasing. Today, sensors are a key technology in a world with an ever-increasing interconnectivity and, thus, essential for the internet of things or Industry 4.0. Gas sensors possess the outstanding capability to provide chemical information from an omnipresent media, the gas phase. The variety of sensor types and oxide materials offer suitable sensor solutions for various applications and sensor capable to operate in various conditions, ranging from ambient air over exhaust systems to industrial ovens at several hundred degrees. The following sections introduce different gas sensors types based on ceramic materials and describe their working principles.

Definitions of Gas Sensors and Characteristic Properties

Gas sensors are chemical sensors, i.e. devices that transform chemical information, which is the concentration of one or several analyte gases, into an analytically useful signal. The sensor consists of a receptor part and a transducer part, which are the two basic functional units of any chemical sensor. The receptor unit transforms the chemical information into a form of energy, which is transformed into a useful analytical signal by the transducer unit subsequently. Ceramic materials are commonly used as receptor unit for gas sensors and in most cases combined with an electrical or electrochemical transducer unit (Hulanicki *et al.*, 1991).

Depending on the transducer unit, the sensor readout is typically based on resistance/conductance, voltage or current measurement (Hulanicki *et al.*, 1991). This raw signal or readout is in many cases used to calculate a sensor signal, which indicates the change with respect to a reference condition. There is no universal way to calculate the sensor signal S from a sensor readout R and one should choose the most suitable way to calculate the sensor signal.

$$S_{diff.} = R_0 - R_{gas} \quad (1a)$$

$$S_{diff.} = R_{gas} - R_0 \quad (1b)$$

$$S_{ratio} = \frac{R_0}{R_{gas}} \quad (2a)$$

$$S_{ratio} = \frac{R_{gas}}{R_0} \quad (2b)$$

One common way of calculating a sensor signal is calculating the difference (equations 1) of the readout in the reference condition (R_0) and the one during gas exposure (R_{gas}). The difference is calculated in a manner to obtain a signal, which has a positive value, e.g. if the readout decreases with increasing analyte concentration, the readout during exposure is subtracted from the readout in the reference condition (Eq. 1(a)). Another common way the calculate sensor signals is calculating the ratio of the readouts (Eq. 2), the obtained ratio is usually calculated in a manner to obtain values larger than 1. Whether the signal is calculated by difference or ratio, strongly depends on the response behavior of the sensor; a set of examples is shown Fig. 1.

The response of the electrochemical gas sensor (Fig. 1(a)) is linear and within the same order of magnitude as the readout in the reference condition, while the chemoresistive sensors (Fig. 1(b)) show a non-linear response and the readout in reference conditions and under analyte exposure differ by several orders of magnitude. When comparing the sensor signals calculated by difference of the electrochemical cells and a chemoresistive gas sensor (Fig. 1(c)), one obtains a suitable calibration curve with distinguishable signals for the electrochemical cells. And the difference in the readout in reference conditions (U_0) is compensated by calculating the signals, showing that both sensors show a very similar behavior. This is different for the chemoresistive gas sensor, which shows no distinguishable signals for different analyte concentrations, i.e., signals obtained by calculating a difference are not suitable for these gas sensors. But when calculating the sensor signals for the chemoresistive sensors as ratios (Fig. 1(d)), one obtains a suitable calibration curve, which displays the different response behavior of the two sensors in this example. A comparison of the numerical values of the sensors signals calculated as difference or ratio (Fig. 1(c) and (d)) shows that the values strongly vary depending on how the signals are calculated and, thus, the mere value of a sensor signal is not a universal measure to compare sensors. In addition to the sensor signals there are other important properties, which are commonly used to describe the performance of gas sensors, namely the sensitivity, selectivity and stability.

Fig. 1 Examples comparing sensor readout and sensor signals for different types of gas sensors. The readout of electrochemical (a) and chemoresistive (b) gas sensors is used to calculate the sensor signals as difference (c) and ratio (d). For the electrochemical cells the signals are calculated from the measured potentials (U_0 and U_{gas}) according to the Eq. 1(b), for the chemoresistive gas sensors from the measured resistances (R_0 and R_{gas}) according to Eqs. 1(a) or 2(a), respectively. For the sake of clarity, not all signals are shown.

Fig. 2 Cross-section of a ceramic bead (a) and schematic measurement circuit (b) of a pellistor.

The sensitivity of a sensor expresses the change in the readout or signal per concentration unit of the analyte, i.e., the slope of the calibration curve (Gründler, 2007). The sensitivity should neither be confused with the sensor signal nor the detection limit. It is given by

$$b = \frac{dS}{dc} \quad (3)$$

where b is the sensitivity, S the sensor signal and c the concentration of the analyte. For linear calibration curves, the sensitivity is constant, while for non-linear calibration curves, e.g. showing a power law relation, the sensitivity depends on the concentration range. In the latter case, the sensor typically shows concentration ranges with higher and lower sensitivity (Danzer, 2007). Directly comparing the sensitivity of different sensors is rather ambitious and a more solid basis for such a comparison is given by the analytical sensitivity, which includes the accuracy (standard deviation) of the measurement as well.

The selectivity of a sensor describes its ability to respond to a group of certain analytes from a larger set of analytes. If the sensor is able to respond to one single analyte in a set of analytes, the sensor is referred to as specific (Gründler, 2007).

The stability of a sensor is its ability to maintain its performance for a certain period of time. Stability is measured by different indicators, such as drift of baseline and sensors signal, as well as retaining its sensitivity, selectivity or response/recovery time (Gründler, 2007; Bochenkov and Sergeev, 2010).

Catalytic Combustion Gas Sensors

A widely applied type ceramic sensor for combustible gases is the pellet resistor or short pellistor. Pellistors are thermometric gas sensors, which transform the heat of a combustion reaction into a measurable electronic readout. Typical applications are detection and monitoring of flammable gases and vapors in air (Gründler, 2007; Bársony *et al.*, 2009).

The active sensing element of a pellistor is a coil of Pt wire, which is embedded in a ceramic bead (e.g., Al_2O_3) and coated with a catalyst layer consisting of noble metals like Pt, Pd or Rh (Fig. 2(a)). The bead is heated to operation temperatures above $450^\circ C$

by passing current through the Pt coil. The gas reception takes place by combusting the analyte, e.g., hydrocarbons such as methane (Eq. (4)), on the catalyst in the presence of atmospheric oxygen.

The heat of combustion ($\Delta_c H^0$) causes a temperature increase of the bead and the embedded Pt wire. Due to the temperature dependence of the specific resistance of Pt, the resistance of Pt wire varies according to Eq. (5).

$$\rho_T = \rho_{T_0} \cdot (1 + 0.0039(T - T_0)) \quad (5)$$

where ρ_T denotes the specific resistance of Pt at the temperature T and ρ_{T_0} the known specific resistance at a reference temperature T_0 . Due to this relation the temperature change caused by the combustion of the analyte is translated into an electronic signal. The bead's temperature is not only changed by catalytic reactions and additional factors, such as fluctuations in gas flow, ambient temperature or heat conductivity of the surrounding atmosphere, as well, cause temperature changes. In order to compensate this effect, an additional bead without a catalytic coating is used as a reference. Both beads are kept in the same environment and, thus, changes in the ambient conditions will affect both. While the catalytic combustion of the analyte, i.e., gas sensing, will only take place on the active bead (Chou, 2000; Gründler, 2007; Bársony *et al.*, 2009).

For the electrical measurement, the active and the reference bead are placed in Wheatstone bridge (Fig. 2(b)). The asymmetric resistance change in the two beads, caused by a catalytic combustion reaction, results in an imbalance in the Wheatstone bridge. The imbalance is measured as a voltage change, which is proportional to the concentration and nature of the combustible gas. For most analytes, pellistors show an almost linear response within a range of 0%–100% of the lower explosion limit. Taking methane as example, a typical pellistor shows a linear increase of the voltage up to 5% of methane, which corresponds to the lower explosion limit. Between the lower explosion limit and the stoichiometric mixture (~ 9% methane in air), the voltage first levels before it steeply increases close to the stoichiometric mixture, where the voltage reaches a maximum. Above the stoichiometric mixture, the voltage decreases. Thus, in oxygen lean conditions, the sensing properties of a pellistor are compromised and the measured signal indicates an analyte concentration, which is lower than the actual one (Chou, 2000; Bársony *et al.*, 2009).

Pellistors are sensitive to a large variety of flammable gases and vapors. On the one hand, this implies a strong cross-interference, i.e., poor selectivity, if several flammable compounds are present. On the other hand, one single sensor is suitable for different analytes or applications. Usually pellistors are calibrated to a certain gas like methane or n-pentane. Correction factors are used to calibrate a pellistor for other analyte gases. Depending on the analyte these factors are larger or smaller than 1. Another source of cross-interference is the concentration of atmospheric oxygen. Pellistors are designed to operate in a range of oxygen excess to the stoichiometric mixture of the analyte gas and oxygen.

Gas Sensors Based on Ion Conducting Metal Oxides

Gas sensors based on ion conducting metal oxides are typically electrochemical sensors, in which the ion conducting metal oxides act as solid electrolyte. Furthermore, metal oxides are used as active electrode materials, e.g., for mixed-potential gas sensors. In all cases, the spontaneous or electrically stimulated analyte-electrode interaction is translated into an analytically useful signal, either by a potentiometric, amperometric or coulometric approach (Hulanicki *et al.*, 1991; Pasierb and Rekas, 2009). Metal oxides used as solid electrolytes have a sufficient thermodynamic stability in the operation conditions, e.g., they do not show degeneration due to redox reactions, and the ionic conductivity should be larger than electronic conductivity ($\sigma_{\text{ion}} \gg \sigma_{\text{electronic}}$). The electronic conductivity depends on the temperature as well as on the oxygen partial pressure and, thus, for a given metal oxide, the ionic conductivity is dominant within a certain regime (electrolytic domain). The mobile ion species in the solid electrolyte is either directly converted from the analyte gas or an equilibrium involving the analyte gas, or formed using an auxiliary phase, which interacts with the analyte gas and is itself an ion conductor (Pasierb and Rekas, 2009; Guth and Wiemhöfer, 2019).

Yttria-stabilized zirconia (YSZ) is a classic example for a solid electrolyte, as it presents a large band gap of 5.1 eV, which limits the electronic conductivity, and is a good oxygen ion conductor at high temperatures (600–1500°C). An electrochemical cell based on an YSZ electrolyte and two porous Pt electrodes (see Fig. 3) can be used as an oxygen concentration cell:

Given that the oxygen partial pressures in both half-cells are different ($p'_{\text{O}_2} > p''_{\text{O}_2}$) and there is no exchange of molecular oxygen through the electrolyte (gas tight metal oxide), the oxygen partial pressure tends to equilibrate. If the outer circuit of the electrochemical cell (6) is closed, the partial pressures are able to equilibrate by the following reactions taking place at the three-phase-boundary (YSZ-Pt-gas phase). In the half-cell with the higher partial pressure (p'_{O_2}), molecular oxygen reacts with oxygen vacancies in YSZ involving electrons provided by the Pt electrode forming lattice oxygen:

In the half-cell with the lower oxygen partial pressure, the opposite reaction occurs and lattice oxygen is converted into molecular oxygen:

Fig. 3 Schematic setup of a potentiometric oxygen sensor based on a solid state electrolyte (brown), with two porous measurement electrodes (blue) based on the same material. The right side shows the general setup; the left side a magnification of the assembly of the electrode and electrolyte.

Fig. 4 Schematic setups of different types of solid state electrolyte gas sensors: Potentiometric gas sensor with a Nernstian behavior (a), mixed-potential gas sensor (b), amperometric gas sensor with a diffusion barrier (c) and coloumetric gas sensor (d). Adapted from Guth, U., 2008. Gas sensors. In: Bard, A.J., Inzelt, G., Scholz, F. (Eds.), *Electrochemical Dictionary*, first ed. Heidelberg: Springer-Verlag Berlin Heidelberg, pp. 293–297. doi:10.1007/978-3-340-74598-3.

The overall reaction of (7) and (8) is the transport of oxygen from the half-cell with the higher oxygen partial pressure to the half-cell with the lower oxygen partial pressure:

In case of a closed circuit, the exchange of oxygen results in a current flow in the outer circuit. In case of an open circuit, the different partial pressures result in a potential difference between the two electrodes. Thus, the readout is either the measured current or potential (Moos *et al.*, 2009; Guth and Wiemhöfer, 2019). Oxygen ion conductors represent one of the most common class of ceramics used for ion conductor gas sensors, but there are other materials, in which other ions such as H^+ , Li^+ or Na^+ are the mobile ion species (Pasierb and Rekas, 2009).

The potentiometric readout of a pair of electrodes, which shows a Nernstian behavior (Fig. 4(a)), is determined by the different chemical potentials of the analytes, i.e., typically partial pressures, in the two half-cells and described by the Nernst equation:

$$E_{\text{eq}} = \frac{RT}{zF} \cdot \ln\left(\frac{p_{\text{gas}}^{\prime\prime}}{p_{\text{gas}}^{\prime}}\right) \quad (10)$$

where E_{eq} is the electro motoric force (EMF) in equilibrium, R the universal gas constant, z the number of transferred electrons, F the Faraday constant and $p_{\text{gas}}^{\prime}$ and $p_{\text{gas}}^{\prime\prime}$ the partial pressures of the analyte gas. Eq. (10) is not only valid for gas mixtures and is as well applicable to molten materials, like liquid metals or molten glasses (Pasierb and Rekas, 2009; Guth and Wiemhöfer, 2019). In simple setups, the reference is a gas mixture with a known analyte concentration, e.g. air as an oxygen reference. An alternative is the use of solid references, e.g., Ni-NiO-mixtures, which are suitable oxygen references (Moos *et al.*, 2009; Guth and Wiemhöfer, 2019).

Oxygen ion conductors like YSZ are not limited to the detection of oxygen and are suitable to detect gases, which are in equilibrium with the oxygen ions in the solid electrolyte, or gases, which are in equilibrium with oxygen (Guth and Wiemhöfer, 2019). For the first case, examples are H_2O or CO_2 , which are in equilibrium with oxygen by Eqs. (11) and (12), respectively. For the latter case examples are water gas mixtures (13) or NO (14).

Furthermore, the measured analyte can differ from the mobile ion species in the solid electrolyte if an auxiliary phase is used on the measurement electrode. An example for an auxiliary phase are CO_2 sensors based on Na^+ ion conductor, e.g., $\text{Na}-\beta''\text{-Al}_2\text{O}_3$ or Na-super-ionic-conductors (NASICON), which use Na_2CO_3 as an auxiliary phase to interact with the analyte gas CO_2 :

For a constant oxygen partial pressure and a constant activity of Na^+ at the reference electrode, which can be achieved by using Na^+ -containing oxides or Na. Such a setup results in a Nernstian behavior and the potential is proportional to the CO_2 partial pressure:

$$E_{\text{eq}} = E^0 + \frac{RT}{2F} \ln(\text{p}_{\text{CO}_2}) \quad (16)$$

where E^0 is the EMF of the cell in standard conditions (Pasierb and Rekas, 2009).

Potentiometric solid electrolyte gas sensors are not limited to electrodes showing a Nernstian behavior, i.e., a potential determined by thermodynamic equilibrium conditions. By using two different, well-selected electrodes (Fig. 4(b)), one obtains a so-called mixed-potential or non-Nernstian setup, operating based on non-equilibrium kinetic principles, i.e., the rate of electrode reactions. A typical mixed-potential setup consists of an oxygen electrode as a reference electrode and a working electrode with a low response to oxygen but a high response to certain analyte gases (H_2 , CO, hydrocarbons or NO_x). The electrodes are arranged either in a gas-symmetric setup, i.e., both exposed to the same gas mixture, or in a non-symmetric setup, in which the reference electrode is exposed to an external reference gas mixture, e.g., air (Moos *et al.*, 2009; Guth and Wiemhöfer, 2019).

Considering for example a carbon monoxide sensitive working electrode and a reference electrode in air, the following electrode reactions are possible for the working (17) and the reference (18) electrode:

In sum, both half-cell reactions correspond to the oxidation of CO to CO_2 (19). The kinetics of both electrode reactions depend on the electrode materials used. The mixed potential is the potential at which both reactions (17 and 18) proceed with the same reaction rate and, thus, the mixed potential depends on the selected electrode material. For example, if reaction (17) is more favored than reaction (18), the oxygen reduction becomes the rate limiting step and non-Nernstian behavior is observed (Miura *et al.*, 1998). A key factor in designing mixed-potential gas sensor is the selection of suitable electrode materials for the working electrode, which determines the sensitivity and selectivity, e.g., by its catalytic properties. Non-Nernstian behavior can be achieved by using metallic working electrodes (e.g., Ni, Ag or Au) or oxides, ranging from binary oxides (e.g. CeO_2 , Nb_2O_5 or SnO_2) over ternary (e.g., EuNbO_4 or LaCrO_3) to mixed oxides ($\text{LaCr}_{0.8-x}\text{Ga}_x\text{O}_{3-\delta}$ or $\text{La}_{1-x}\text{Sr}_x\text{Cr}_{1-y}\text{Ga}_y\text{O}_{3-\delta}$) used as working electrode. However, the selection of electrode materials is largely based on an empirical process rather than knowledge-based selection derived from understanding of the fundamental processes in details (Guth and Wiemhöfer, 2019).

For mixed-potential gas sensors, the quantitative relation of the EMF and the analyte gas concentration is given by the theory by N. Miura, which is based on the Butler-Volmer equation. According to Miura's theory, there is a logarithmic relation between the measured mixed potential and the analyte concentration equation (Miura *et al.*, 1998):

$$E_{\text{mix}} \propto \ln(\varphi_{\text{analyte}}) \quad (20)$$

The behavior of different potentiometric solid electrolyte gas sensors during the exposure to propane in a low oxygen background is shown in Fig. 5. Thermodynamically controlled electrodes with a catalytically active material are characterized by a lambda-leap (Fig. 5, blue line); at the reactive electrode surface, the non-equilibrated gas mixture is fully combusted to H_2O and CO_2 . Thus, in oxygen rich mixtures a low potential is measured, which drastically increases around the stoichiometric mixture. Using catalytically inactive electrode materials, e.g., LaCrO_3 , it is possible to selectively measure the free oxygen concentration in the gas mixture, i.e., the voltage is independent of combustible gases in the gas mixture (Fig. 5, gray line). According to Eq. (20), kinetically controlled (non-Nernstian) electrodes show logarithmic dependence on the concentration of the combustible gas (Fig. 5, red line).

An amperometric readout (Fig. 4(c)) of gas sensor based on ionic conductors is achieved by operation voltages, at which the electrode reaction is solely limited by the gas transport. Typically the rate of gas transport is limited by using a small hole or porous ceramic as a diffusion barrier. The measured current, I_{lim} , depends on fixed parameters, such as the dimensions of the diffusion barrier, the diffusion constant, D_{gas} , and the mole fraction, x_{gas} , of the analyte gas:

Fig. 5 Cell voltages of a pair of Nernstian electrodes (blue) and a mixed potential gas sensor (red) as a function of the propene concentration in an oxygen background of 1.5% vol. Adapted from Guth, U., Zosel, J., 2004. Electrochemical solid electrolyte gas sensors -Hydrocarbon and NO_x analysis in exhaust gases. *Ionics* 10 (5–6), 366–377. doi:10.1007/BF02377996.

$$I_{lim} = -\frac{zFD_{gas}Ap}{RTL} \ln(1 - x_{gas}) \quad (21)$$

For a small hole, the dimensions of the diffusion barrier are the area, A , and the length, L . For low analyte gas concentrations ($x_{gas} \ll 1$), Eq. (21) simplifies to:

$$I_{lim} = \left(-\frac{zFD_{gas}Ap}{RTL} \right) x_{gas} = const \cdot x_{gas} \propto p_{gas} \quad (22)$$

Thus, for low analyte gas concentrations, there is a linear relation between the analyte gas and the measured current. Amperometric ion conductor gas sensors are used as wideband lambda probes in internal combustion engine cars and allow the simultaneous detection of O₂, NO_x and hydrocarbons (Guth and Wiemhöfer, 2019).

Another measurement principle based on a current readout is the coulometric operation (Fig. 4(d)), which is based on Faraday's law:

$$n = \frac{Q}{zF} = \frac{I_F t}{zF} \quad (23)$$

where n is the amount of the analyte gas, Q is the charge, I_F the current and t the time. Strictly following Faraday's law, the current is directly proportional to the amount of the analyte gas reacting and passing through the solid electrolyte. Gas measurements can be either done by titration or in a gas flow. If the measurement is done by titration, the amount of the analyte gas is obtained by integration over time:

$$n = \frac{Q}{zF} = \frac{1}{zF} \int_{t_1}^{t_2} (I - I_{Base}) dt \quad (24)$$

where I_{Base} is the current in the absence of any analyte gas in the mixture. In a continuous gas flow, the sensors consist of a pump cell and a potentiometric cell and the measured current depends on the analyte gas concentration, the molar volume of the analyte and flow rate of the gas:

$$x_{gas} = \frac{I - I_r}{zF} \frac{V_m}{dV/dt} \quad (25)$$

where x_{gas} is molar fraction of the analyte gas, I_r is the residual current due to the electronic contribution to the conduction, V_m is the molar volume of the analyte gas and dV/dt is the flow rate.

Coulometric gas sensors based on ionic conductors can be used to detect a large variety of reducing (H₂, hydrocarbons) or oxidizing gases (oxygen) and have the advantage that there is no need for calibration of the sensor, since they strictly follow Faraday's law (Guth and Wiemhöfer, 2019).

Gas Sensors Based on Semiconducting Metal Oxides

Chemoresistive gas sensors based on semiconducting metal oxides (SMOX) represent one of the most versatile category of gas sensors. Their small size, relatively low power consumption and cost-efficient production, along with their high sensitivity, long lifetime and various methods to modify their selectivity, are the basis for their widespread success. At elevated and high temperatures SMOX show distinct changes of their conductivity due to changes in the surrounding atmosphere. Their sensing

Fig. 6 Possible reaction path of the oxygen exchange reaction of a bulk-active SMOX used as chemoresistive oxygen sensor. Adsorbed species are labeled with the suffix ads and their charge is indicated by minus. Bulk species are represented using the Kröger-Vink notation.

mechanisms and gas sensing performances strongly depend on the nature of the material, its microstructure and the operation conditions (Kim *et al.*, 2013; Neri, 2015).

There are two major types of chemoresistive SMOX. In the first case, the SMOX comes to equilibrium throughout the whole solid, i.e., surface and bulk of the material. This is typically achieved by sufficiently high operation temperatures ($> 700^\circ\text{C}$). These bulk-active gas sensors show a dependence of conductivity on the oxygen partial pressure. In the second case, the bulk of the SMOX does not come to equilibrium with the surrounding atmosphere. This situation is typically found for SMOX operated at temperatures below 400°C . The conductivity of surface-active SMOX depends on charged species adsorbed on the surface. The equilibrium between the adsorbed charged species and the gas phase is influenced by various reactive gases, even at trace levels, and, thus, makes surface-active SMOX highly sensitive to various analyte gases (Kim *et al.*, 2013).

Bulk-Active SMOX

At high temperatures ($> 700^\circ\text{C}$), an exchange reaction of oxygen in the gas phase and the SMOX lattice takes place. This reaction includes the adsorption of atmospheric oxygen, its ionization and dissociation, as well as the diffusion of oxygen/oxygen vacancies within the SMOX. However, the actual sequence of these steps is often indistinguishable and various pathways may be possible (Maier, 1993; Kim *et al.*, 2013). An example for the oxygen exchange reaction is given in Fig. 6. Typical examples of SMOX showing such an oxygen exchange at high temperatures are SrTiO_3 , TiO_2 or SnO_2 (Choi and Tuller, 1988; Maier and Göpel, 1988; Nowotny *et al.*, 2008).

The overall reaction of the oxygen exchange is summarized as follows, using the Kröger-Vink notation of point defects:

where $V_{\text{O}}^{\cdot\cdot}$ are double ionized oxygen vacancies, e' are electrons and $\text{O}_{\text{O}}^{\times}$ are oxygen ions in an oxygen lattice site with no charge difference to ideal lattice structure. For sake of simplicity, the involved metal ion species are neglected. For n-type SMOX, electrons are taken from the conduction band. If the concentration of electrons in the conduction band gets smaller, i.e., the Fermi energy is close to the valence band, the electron neutrality of the reaction is preserved by extracting electrons from the valence band, creating holes (h') in the valence band. In this case, the exchange reaction of oxygen is:

Due to the equilibrium between electrons and holes both reactions (26 and 27) are linked and can be formally described by one of the reactions. However, both reactions occur at the same time and their contribution to the oxygen exchange reaction depends on the oxygen partial pressure. In an oxide the concentration of oxygen vacancies is by far smaller than the concentration of lattice oxygen ($V_{\text{O}}^{\cdot\cdot} \ll \text{O}_{\text{O}}^{\times}$) and the concentration of lattice oxygen is considered to be constant. Thus, the concentration of oxygen vacancies and electrons is proportional to the oxygen partial pressure:

$$[e']^{-4} \cdot [V_{\text{O}}^{\cdot\cdot}]^{-2} \propto p_{\text{O}_2} \quad (28)$$

Neglecting the ionic contribution to the conductivity of the SMOXs, the conductivity (σ) depends on the concentration and mobility (μ) of electrons and holes:

$$\sigma = e(\mu_{e'} \cdot [e'] + \mu_{h'} \cdot [h']) \quad (29)$$

where e is the elementary charge. Depending on the majority charge carrier a SMOX will show n-type ($[e'] \gg [h']$) or p-type ($[e'] \ll [h']$) behavior.

The conductivity of a bulk-active SMOX as a function of the oxygen partial pressure is generally described by the following equation:

$$\sigma \propto [e'] \propto \exp\left(-\frac{E_A}{kT}\right) \cdot (p_{\text{O}_2})^{\frac{1}{m}} \quad (30)$$

where E_A is the activation energy of the defect formation during the oxygen exchange reaction and $\frac{1}{m}$ an exponent, which depends

Fig. 7 Conductivity of different bulk-active SMOX as a function of the oxygen partial pressure at different operation temperatures. With increasing oxygen partial pressure, the conductivity changes from n-type ($m = -1/4$) to p-type ($m = +1/4$) behavior. Reprinted from Kim, I.D., Rothschild, A., Tuller, H.L., 2013. Advances and new directions in gas-sensing devices. *Acta Materialia* 61 (3), 974–1000. doi:10.1016/j.actamat.2012.10.041.

on the chemistry taking place at a certain oxygen partial pressure. Depending on the oxygen partial pressure, different values for m are found. For low oxygen partial pressure, the electrons are the majority charge carrier and their concentration is larger than the acceptor impurity concentration, which can be neglected and m equals -6 . In intermediate oxygen concentrations, the concentration of electrons is much smaller than the acceptor impurity concentration. The oxygen vacancy concentration is approximately equal to the constant concentration of acceptor impurities. As long as electrons are the majority charge carrier, i.e., as long as the reaction described in Eq. (26) dominates, m equals -4 . With the proceeding incorporation of atmospheric oxygen the concentration of electrons in the conduction band decreases until formation of holes (27) dominates the oxygen exchange. In this situation the conductance is dominated by holes ($[e'] \ll [h]$), i.e., the SMOX transitions from an n-type to a p-type semiconductor and m equals $+4$. The transition from n-type to p-type conduction and the change in the relation between conductance and oxygen partial pressure is observed for various materials (see Fig. 7).

At high oxygen concentrations, the holes are still the dominant charge carrier and their concentration is determined by the constant concentration of acceptor impurities and, thus, the conductance is independent of the oxygen partial pressure (Choi and Tuller, 1988; Nowotny *et al.*, 2008).

As shown in Eq. (30) and Fig. 7, the conductance not only depends on the oxygen partial pressure but is influenced by the operation temperature as well. Thus, using bulk-active SMOX as oxygen sensors, requires an accurate and stable temperature control to avoid an interfering effect of temperature offsets or fluctuations. Another, yet more exceptional, approach achieves a temperature independence by tailoring the material in fashion that two opposite effects balance each other. Such an example is $\text{SrTi}_{0.65}\text{Fe}_{0.35}\text{O}_3$, which is shown in Fig. 7 (Kim *et al.*, 2013).

Oxygen sensing with bulk-active SMOX is based on the exchange reaction of atmospheric oxygen and lattice oxygen of the SMOX, which traps or releases electrons from the solid and, thus, alters the charge carrier concentration of the whole material. The oxygen exchange reaction and the subsequently changed charge carrier concentration are the reception process. The transduction, i.e., translating the change in the charge carrier concentration into an electrical signal, is implemented by a resistance measurement.

Assigning a SMOX as such to the bulk-active or surface-active type is rather ambiguous; depending on the operation temperature, the same SMOX can be either a bulk-active or surface-active gas sensing material. For example, SnO_2 is the most widely used SMOX for surface-active gas sensors, but operated at sufficiently high operation temperatures ($\sim 600^\circ\text{C}$), the material's bulk equilibrates with atmospheric oxygen and the conductance is proportional to the oxygen partial pressure (Maier and Göpel, 1988; Ihokura and Watson, 1994).

Surface-Active SMOX

For bulk-active SMOX, the interaction with the gas phase, namely atmospheric oxygen, affects the whole volume of the material. For surface-active SOMX, which are operated at intermediate temperatures ($100\text{--}400^\circ\text{C}$), the interaction with the gas phase only affects the surface region of the material, while the bulk remains unaffected by the atmosphere. The oxygen exchange reaction (Fig. 6) will only change adsorbed species and the composition of the surface. The sequence and major species of the oxygen exchange at intermediate temperatures were discussed by various authors and still remain under discussion (Barsan and Weimar, 2001; Gurlo, 2006; Kim *et al.*, 2013). For key n-type SMOX, namely SnO_2 , WO_3 and In_2O_3 , the current model describes the interaction with atmospheric oxygen as the formation and cancelation of oxygen vacancies at the surface of the material (Degler *et al.*, 2019). Using a modified Kröger-Vink notation (+ and $-$ to indicate the charge with respect to the lattice position) to avoid confusion with the bulk oxygen exchange, the oxygen exchange at intermediate temperatures can be described as follows:

where V_{O}^{++} is a surface oxygen vacancy, O_{O} surface oxygen and k_{ads} or k_{des} the rate constants of the adsorption or desorption of oxygen, respectively. The process described in Eq. (31) is referred to as ionosorption, since the adsorption involves a charge transfer between the adsorbed species and the solid. The concentration of ionosorbed oxygen depends on the oxygen partial pressure, the number of adsorption sites, i.e., oxygen vacancies, and electrons available at the surface. The total number of ionosorbed species is limited to a fraction of a monolayer (10^{-5} to 10^{-3}) by the so-called Weisz limitation (Weisz, 1953). Furthermore, the concentration of ionosorbed oxygen is influenced by the partial pressure of oxygen, the number of electrons available at the surface and the presence of other reactive gases, first and foremost reducing gases, which are oxidized by surface oxygen. A simple example is the oxidation of CO by the ionosorbed oxygen:

The oxidation reaction of other reducing gases or vapors, e.g., alcohols or other volatile organic compounds, may result in a more complex surface chemistry, including partial oxidation products. Oxidizing gases, such as NO_2 , have as well an impact on the surface composition of SMOX and the total number of ionosorbed species. Interfering compounds, especially water vapor, have a large impact on the surface chemistry of SMOX, competing for the same sites or reaction partners and inhibiting surface reactions. The nature of all surface reactions is determined by various parameters; the SMOX itself and the operation temperature have a large impact on the reactions with reducing or oxidizing gases as well as the influence of interfering compounds (Sänze and Hess, 2014; Degler *et al.*, 2015).

According to the Eqs. (31) and (32), the surface concentration of ionosorbed oxygen, or vice-versa oxygen vacancies, is determined by the composition of the surrounding atmosphere, namely the concentrations of oxygen and reducing gases. Only the surface of the material is changed by these reactions and, thus, the oxygen vacancies concentration at the surface and in the bulk of the material varies and results in the formation of space charge layers. If the oxygen vacancy concentration at the surface is lower than the one in the bulk ($[V_{\text{O}}^{++}]_{\text{surf}} < [V_{\text{O}}^{++}]_{\text{bulk}}$) an electron depletion layer is formed at the surface, which is described by an upwards band bending ($eV_s > 0$). While if the oxygen vacancy concentration at the surface is higher than the one in the bulk ($[V_{\text{O}}^{++}]_{\text{surf}} > [V_{\text{O}}^{++}]_{\text{bulk}}$) an electron accumulation layer is formed, which corresponds to a downwards band bending ($eV_s < 0$). If both vacancy concentrations are equal ($[V_{\text{O}}^{++}]_{\text{surf}} \approx [V_{\text{O}}^{++}]_{\text{bulk}}$), there is no band bending caused by the reactions with the atmosphere. In the absence of an initial band bending, e.g., due to additional donor or acceptor states, this situation is referred to as flat band situation (Degler *et al.*, 2019).

The surface band bending affects the electron concentration at the surface. If all donors are fully ionized (Schottky approximation), the surface concentration of electrons in a depletion layer is described by the following Boltzmann distribution:

$$n_s = n_b \cdot \exp\left(-\frac{eV_s}{k_B T}\right) \quad (33)$$

where n_s and n_b are the surface or bulk concentration of electrons, respectively, e is the elementary charge of an electron, V_s is the surface band bending, k_B is the Boltzmann constant and T the absolute temperature (Barsan and Weimar, 2001).

A typical surface-active SMOX gas sensor is based on a porous layer of SMOX grains, which are connected, but show no sintering necks. In this case, the resistance of the full layer R is determined by the resistance of the grain-grain-boundary, which depends on the surface concentration of electrons n_s , which, according to Eq. (33), exponentially depends on the surface band bending V_s :

$$R \propto n_s \propto \exp\left(\frac{eV_s}{k_B T}\right) \quad (34)$$

Surface-active SMOX gas sensors typically show strong responses, i.e. resistance changes of one or more orders of magnitude, to changes in the atmosphere and the sensor signals are calculated as a ratio (Eq. 2). In case of an n-type SMOX exposed to a reducing gas (Eq. 2(a)) and using Eq. (34), one obtains the following relation for the sensor signal:

$$S = \frac{R_0}{R_{\text{gas}}} \propto \frac{\exp\left(\frac{eV_{s,0}}{k_B T}\right)}{\exp\left(\frac{eV_{s,\text{gas}}}{k_B T}\right)} = \exp\left(\frac{e\Delta V_s}{k_B T}\right) \quad (35)$$

where R_0 is the resistance in the reference condition and R_{gas} the resistance under gas exposure. As shown in Eq. (35), the sensor signal is proportional to changes in the surface band bending, caused by the space charge layer created by the difference in the oxygen vacancy concentration or other ionosorbed species, which is determined by the surface chemistry (Eqs. (31) and (32)).

The Eqs. (33) to (35) describe the situation for an electron depletion layer. In case of an electron accumulation layer, a different relation is valid (Barsan *et al.*, 2010):

$$S = \frac{R_0}{R_{\text{gas}}} \propto \frac{\exp\left(\frac{eV_{s,0}}{2k_B T}\right)}{\exp\left(\frac{eV_{s,\text{gas}}}{2k_B T}\right)} \propto \exp\left(\frac{e\Delta V_s}{2k_B T}\right) \quad (36)$$

Fig. 8 Working principle of surface-active n-type SMOX showing the gas reception (left) and transduction (right) in four important conditions: Formation of an accumulation layer in oxygen-lean conditions (a), flat band situation (b) and depletion layer in the presence (c) and absence (d) of an analyte gas in an oxygen excess. The unaffected bulk region is shown in orange, the depletion layer in yellow and the accumulation layer in brown. Reprinted from Degler, D., Weimar, U., Barsan, N., 2019. Current understanding of the fundamental mechanisms of doped and loaded semiconducting metal oxide-based gas sensing materials. *ACS Sensors*. doi:10.1021/acssensors.9b00975.

Accumulation layer controlled conduction is typically found for p-type SMOX in ambient conditions, i.e., high oxygen backgrounds (Barsan *et al.*, 2010; Kim and Lee, 2014). For n-type SMOX, accumulation layers occur when the SMOXs are exposed to reducing gases in low oxygen backgrounds or when being exposed to high concentrations of reducing gases in humid atmospheres (Barsan *et al.*, 2011; Barsan *et al.*, 2015). The gas sensing mechanism for pristine n-type SMOX is summarized in Fig. 8.

The gas sensing mechanism (Fig. 8) of pristine surface-active SMOX involves a series of surface reactions, which involve the formation or cancelation of surface oxygen vacancies or the formation of other charged surface species and results in the formation of a space charge layer, which determines the surface concentration of electrons. The interaction of oxygen and analyte gases and how these reactions influence the surface concentration of electrons largely depends on the chemical and electrical properties of a specific SMOX and can be further influenced by doping or loading with additives. Similar to bulk-active SMOX, chemical reaction and the subsequent changes in the charge carrier concentration represent the reception mechanism, but with one important difference that only the surface of the material is affected. The transduction is implemented by a resistance measurement typically. Since only the surface of the material is affected, the conduction through the sensing layer, i.e., the transduction, is strongly influenced by the microstructure of the material.

Introducing additives, typically other main or transition group elements, into SMOX materials is widely used to improve the gas sensing properties of surface-active SMOX. Additives form different structures, ranging from doping the SMOX, i.e., incorporating single foreign atoms/ions in the SMOX lattice, to loadings, i.e., separate metallic or oxide phases attached to SMOX surface. Dopants and loadings largely influence the chemical and electrical properties of the SMOX, and the resulting sensitization effect of an additive has a chemical and electrical contribution, rather than solely altering the chemical or electrical properties (Degler *et al.*, 2019).

One of the goals of additives is the improvement of the catalytic activity of the typically poorly reactive SMOX. However, solely an increased reactivity does not necessarily result in an increased sensor effect. First, the catalytically enhanced reaction must affect the charge carrier concentration of the SMOX to contribute the gas reception. Second, this change must be reversible and sufficiently strong. The latter point marks a major difference between a good chemoresistive gas sensor and an efficient catalyst. A

Fig. 9 Proposed sensitization mechanisms of additives in surface-active SMOX materials used as chemoresistive gas sensors. Dopants (a) change the electronic properties of the SMOX, indicated by the lighter color around the additives, and affect the surface chemistry by creating new surface sites. Loadings either change the gas sensing mechanism by a spillover mechanism (b), which increases the surface reactivity, or a Fermi-level control mechanism (c), which is based on the electronic coupling of the SMOX and additive.

sensor requires a temporary change of the material's properties, which are result in the sensor signal, while an efficient catalyst requires a swift recovery of the initial, reactive state, in order to obtain a high turnover rate. Thus, SMOX-based gas sensors and catalysts typically have opposed requirements to the chemical reaction taking place (Müller *et al.*, 2018; Degler *et al.*, 2019).

To understand the effect of additives of SMOX different models were developed, which largely depend on the structure of the introduced additive. Dopants (Fig. 9(a)) could have an electrical or chemical effect as well as both. Taking a foreign cation replacing a lattice cation as example, this could result in the formation of additional donor or acceptor states, depending on the relative charge of the foreign ion with respect to the original lattice ion. The electrical effect will be strongly influenced by the distribution of the foreign ions in the SMOX. The distribution involves the concentration as well as the oxidation state of dopants and determines whether dopants cause a shift of the Fermi level in the whole material or an intrinsic band bending at the surface. Dopants at the surface of the SMOX material may offer new reaction sites with different properties than the ones on the original SMOX and, thus, alter the reactivity (Degler *et al.*, 2019).

Loadings are present as metallic or oxide clusters at the SMOX surface (Fig. 9(b) and (c)), depending on the material preparation as well as the operation condition of the gas sensor. One typical sensitization mechanism of loadings is the spillover of one of the species involved in the surface chemistry (Fig. 9(b)), which results in an increased reactivity of the surface, i.e., is supposed to enhance the gas reception. Spillover sensitization is typically assigned to metallic loadings, which are not electronically coupled with the supporting SMOX, and involve either the spillover of the analyte, usually a reducing gas, or molecular oxygen. The spillover of a reducing gas involves the adsorption on the loading, possibly an activation or partial reaction of the reducing gas, and the transfer to the SMOX surface, where the reducing gas reacts with oxygen from the SMOX surface. The spillover of oxygen has a more ambivalent effect on the gas reception: on the one hand, the increased oxygen coverage on the SMOX surface offers more reaction sites for reducing gases, increasing the probability of a successful interaction, i.e., gas reception. On the other hand, the increased adsorption of oxygen favors the cancelation of oxygen vacancies, i.e., compensates the gas reception.

The other major sensitization mechanism of loadings is the so-called Fermi-level control mechanism (Fig. 9(c)), which has a chemical and an electrical contribution to the sensitization effect. The electronic contribution implies different work functions of the SMOX and loading, which result in an alignment of the two Fermi levels. Consequently, the Fermi level of the SMOX is pinned by the loading and in the vicinity of the loading the space charge layer is determined by the electronic coupling with the loading. The magnitude of the space charge layer changes if the work function of the loading changes, e.g., due to changes in its composition, which can be caused by surface reactions. The chemical contribution is related to the shift of the reaction with the analyte gas from the SMOX to the loading. This shift is caused by the generally higher reactivity of various loadings, such as oxides of Rh, Pd, Ag or Pt, and a deactivation of the SMOX near the loading. The deactivation originates from the typically high band bending induced by the electronic coupling, which limits the surface concentration available for oxygen ionosorption (Eq. (31)), therefore decreasing the number of reactive oxygen available to oxidize the analyte gas (Eq. (32)). In case of the Fermi-level control mechanism, the electrical and chemical effects of the loading result in a control of the space charge layer in the SMOX by the composition of the loading, which changes when reacting with analyte gases. Since the gas reception is controlled by the loading, it is possible to strongly change the selectivity of a gas sensing material (see Fig. 10). The spatial limitation of the electronic coupling results in a strong dependency of the sensitization effect on the concentration, size and distribution of the loading (Degler *et al.*, 2019).

Introducing additives in SMOX is a powerful tool to influence the gas sensing properties by changing the gas reception. There are further parameters having an impact on the gas sensing properties of surface-active SMOX. The morphologies and micro-structure of the sensing material have a strong impact on the conduction in the sensing layer, i.e., the transduction, and therefore on the gas sensing properties.

The morphology of the sensing layer determines the accessibility of gases into the sensing layer. In a compact sensing layer or for a single crystalline SMOX (Fig. 11(a)), gases are not able to access the volume of the sensing material and only will interact with the outermost region of the gas sensing layer. Thus, the inner volume is not affected by the gas phase. For an n-type SMOX, the omission of oxygen ionosorption from the gas phase prevents the formation of a depletion layer and consequently the resistance in the volume will be lower. Two parallel resistors represent this situation in the equivalent circuit shown in Fig. 11. One is

Fig. 10 Effect of different loadings on SnO₂-based gas sensing materials. Metallic Au-loadings (a) sensitize the material by an oxygen-spillover, increasing the general reactivity and having minor impact on the selectivity towards the different analyte gases. PdO-loadings (b) sensitize the material by a Fermi-level control mechanism, having a stronger impact on the selectivity since the gas response is controlled by the PdO loading. The sensor response of the pristine SnO₂ is shown in blue as comparison for the loaded materials (red). Measurements in dry air are plotted with dashed lines and empty symbols, measurements in humid air (50%RH) are plotted with straight lines and filled symbols. Fig. 11 Schematic representation of the charge transport in different surface-active SMOX layers: Compact layer (a, top), single crystal nanowire (a, middle) and the corresponding equivalent circuit for these two layer morphologies (a, bottom); The conduction paths is represented by a series the two electrode contacts (blue), which are determined by the work function difference of the two materials, and two parallel resistors representing the conductivity of the surface (yellow) and bulk (orange). Porous layer of SMOX grains with a radius larger than the Debye length (b, top) and the corresponding equivalent circuit (b, bottom); the conduction paths are represented by a series of the two electrode contacts and a repetition of a resistor, which represents the bulk of a SMOX grain, and the grain – grain interface (GI), which is represented by a parallel resistor and capacitor. Porous layer of SMOX grains with a radius smaller than the Debye length (c, top) and the corresponding equivalent circuit (c, bottom); the conduction paths are represented by the two electrode contacts and a series of resistors representing each fully depleted grain. Reprinted from Degler, D., Weimar, U., Barsan, N., 2019. Current understanding of the fundamental mechanisms of doped and loaded semiconducting metal oxide-based gas sensing materials. *ACS Sensors*. doi:10.1021/acssensors.9b00975.

representing the surface resistance, which is sensitive to changes in the gas phase, and one the bulk resistance, which is not affected by the gas phase, but mainly contributes to the conduction. For compact layers or single crystals, only a small fraction of the SMOX material contributes to the gas sensing effect and the changes in the less conductive surface region result only in a minute change in the overall resistance. In contrast, in porous layers (Fig. 11(b) and (c)), the gases access the whole volume of the sensing layer and

evenly influence the SMOX material. However, the consumption of the analyte gas can result in a concentration gradient within the sensing layer and gradually decrease the sensing effect in the volume of the gas sensing layer (Barsan and Weimar, 2001).

For porous layers, the size and interface of the SMOX grains additionally influence the transduction. The size of a SMOX grain does not only consider the geometrical size, i.e., grain diameter d , but rather considers the ratio of the grain diameter and the size of the depletion layer, or Debye length λ_D . Grains are large if the diameter is larger than twice the Debye length ($d > 2\lambda_D$), while grains are small if the diameter is smaller than twice the Debye length ($d < 2\lambda_D$). In case of large grains, the current will preferentially pass through the bulk of the grain, but at each grain-grain-boundary, the electrons have to pass the depletion layer. The situation at the grain-grain-boundary resamples a back-to-back Schottky barrier, which determines the conduction. The corresponding equivalent circuit for an n-type SMOX with an electron depletion layer (Fig. 11(b), bottom) comprises of a series of a resistor with a parallel capacitor, which represents the grain-interface, with a serial resistor, which represents the bulk of a grain. In case of small grains, the SMOX grains are fully depleted and the charge transport is limited by the surface concentration of electrons. The corresponding equivalent circuit is represented by a series of resistors (Fig. 11(c), bottom), each one representing one SMOX grain (Barsan and Weimar, 2001). Discussions focusing on p-type SMOX are given elsewhere (Barsan *et al.*, 2010; Kim and Lee, 2014).

Surface-active SMOX typically display a power-law relation between the analyte concentration and the obtained sensor signal. Thus, surface-active SMOX are often highly sensitive to trace amounts of analytes, but have a low sensitivity for high analyte concentrations. Pristine, as well as most of the doped and loaded, SMOX react with a large variety of analyte gases and one sensor is often suitable for detection of various gases. This lack of selectivity is one of the major drawbacks of surface-active SMOX. In order to overcome these disadvantages, several strategies are possible, including using filters, modulating the operation temperature of the sensor or building sensor arrays, which consist of several sensor elements showing an orthogonal response pattern. A related drawback is the strong interference of water vapor, which is present in most ambient environments. Chemoresistive gas sensors based on SMOX have a high life expectancy of 10 years or more. However, their stability and reliability suffer from operation in oxygen lean conditions, or the exposure to compounds poisoning the gas sensors, such as silicon oil. Despite the several drawbacks, surface-active SMOX are suitable for various applications ranging from the detection of harmful over substances process monitoring to applications in health and comfort.

Conclusion

Gas sensors based on ceramic materials include a large variety of different sensor principles. Ceramic gas sensors cover a large range of applications, but for certain environments, some materials or sensor principles are favorable or some even not suitable. Thus, all the presented types of gas sensors are currently found in applications, e.g., the detection of flammable gases by pellistors or chemoresistive sensors (surface active-SMOX) or controlling the exhaust catalysts in internal combustion engine cars using potentiometric or amperometric sensors based on solid-state ion conductors. With the increasing importance of smart and connected systems, gas sensors will gain importance as they can provide chemical information from the surrounding environment, i.e., directly from or via the gas phase. The emerging of Industry 4.0 and the Internet of Things pose new requirements on the sensors' sensitivity, selectivity and stability as well as their suitability for certain applications, e.g. miniaturized systems for small sizes and low power consumption, or highly robust sensor which operate in harsh environments. All these requirements are demanding tasks for the development of sensor technology on various levels, including new materials, new approaches to design and manufacture sensor devices, develop sensor systems and analyze the data obtained by sensors. Compiling with these tasks requires a profound understanding of the fundamental processes of ceramic gas sensors to find knowledge-based and target-oriented solutions. Thus, the development of ceramic gas sensors should always comprise the development of new materials, devices or systems, as well as investigating and understanding their fundamental principles.

Introduction

The pyroelectric effect is the change in electrical dipole moment occurring in a polar dielectric due to a change in its temperature. As a consequence of this effect, a detectable current can be made to flow in an external circuit connected to a piece of polar dielectric, allowing the temperature change to be sensed. This effect has been known for many years (Lang, 1999), and since about 1960 it has been extensively studied for the detection of radiation in the two “atmospheric window” infrared radiation (IR) bands of 3–5 μm and especially 8–14 μm . The ambient-temperature operation of pyroelectric detectors gives them a number of important advantages over the cryogenically cooled photon detectors such as mercury cadmium telluride or indium antimonide. Pyroelectric detectors have found a huge range of applications in products ranging from fire alarms to intruder detectors, in instrumentation such as gas analysis, and in thermal imaging. Detectors have been demonstrated that work from the visible through the IR to submillimeter and millimeter wavelengths. They have also been used at radiation modulation frequencies from a few hertz to many gigahertz.

The pyroelectric coefficient is a vector $\bar{p}$, equal to the rate of change of the spontaneous polarization $\bar{P}_S$ with temperature (T):

$$\Delta \bar{P}_S = \bar{p} \Delta T \quad (1)$$

Fig. 1 shows a schematic diagram of a pyroelectric IR detector. It consists of a thin piece of pyroelectric material (the “element”), which has conducting electrodes (usually on its major surfaces) such that there is a component p of $\bar{p}$ perpendicular to the electrodes. These have area A . The pyroelectric charges generated by a change in element temperature can be detected as a current, i_p , flowing in an external circuit such that:

$$i_p = Ap \{dT/dt\} \quad (2)$$

dT/dt is the rate of change of the element’s temperature with time. Thus pyroelectric devices are coupled to the changes of any input energy flux that generate a change in element temperature. Typically, an IR detector will be constructed as shown schematically in Fig. 1, with a high-input impedance amplifier (usually a MOSFET) connected to the element. The largest pyroelectric effects are generally observed in the class of polar dielectric materials known as ferroelectrics (Lines and Glass, 1977). A major advantage of these is that they can be used in polycrystalline form, because they can be electrically poled. This produces a net spontaneous polarization and thus a net pyroelectric effect.

The pyroelectric effect and devices using them have been extensively reviewed previously (see, e.g., Putley, 1970; Whatmore, 1986). Hence, this chapter will briefly review the ways in which the physics of pyroelectric radiation detector operation affects the choice of materials to use in them, discuss the range of such materials, with specific reference to ferroelectric crystals, ceramics, and thin films, and their uses in one of the most exciting recent applications of the devices to emerge into practical applications in the last 10 years, namely uncooled thermal imaging.

Pyroelectric IR Detectors and Materials Figures-of-Merit

The analysis of a pyroelectric detector, shown schematically in Fig. 1, requires consideration of both the thermal and electrical circuits. Radiation with power $W(t)$ sinusoidally modulated at a frequency ω so that $W(t) = W_0 e^{i\omega t}$ is incident on the surface of the element (area A and thickness d), which has emissivity η . The element has a thermal capacity H and a thermal conductance to the

Fig. 1 Schematic diagram of a pyroelectric detector element.

surroundings G_T giving a thermal time constant $\tau_T = H/G_T$. A high-input impedance field effect transistor (FET) used as a source follower amplifier amplifies the electrical signal produced. R_G is the gate resistor, giving an electrical time constant $\tau_E = R_G(C_E + C_A)$ where C_E is the capacitance of the element and C_A the capacitance of the amplifier.

The τ_T and τ_E are the fundamental factors that determine the frequency response of the detector. It can be shown that the pyroelectric current, i_p , generated per watt of input power (the current responsivity R_i) is:

$$\frac{i_p}{W_o} = R_i = \frac{\eta p A \omega}{G_T \sqrt{(1 + \omega^2 \tau_T^2)}} \quad (3)$$

The voltage responsivity of the detector shown in Fig. 1 is simply derived from i_p and the electrical admittance (Y) presented to it. The pyroelectric voltage (V_p) generated on the gate of the FET (and therefore the output voltage V_o for a unity amplifier gain) is given by i_p/Y and the voltage responsivity is R_V where:

$$R_V = \frac{i_p}{Y W_o} = \frac{R_G \eta p A \omega}{G_T \sqrt{(1 + \omega^2 \tau_T^2)} \sqrt{(1 + \omega^2 \tau_E^2)}} \quad (4)$$

The responsivity is maximized by minimizing the element's thermal capacity (i.e., making it thin) and by minimizing G_T (i.e., thermally isolating it from its surroundings).

If the element capacitance C_E is large compared with C_A then R_V reduces to:

$$R_V = \frac{\eta p}{c' \epsilon \epsilon_o A \omega} \quad (5)$$

where c' is the volume-specific heat, ϵ_o is the permittivity of free space, and ϵ is the relative permittivity of the pyroelectric material. For such a detector, the response is proportional to F_V :

$$F_V = \frac{p}{c' \epsilon \epsilon_o} \quad (6)$$

Eq. (6) only contains parameters describing properties of the pyroelectric material, and is therefore a figure-of-merit (FOM), which can be used to compare different materials for their potential voltage responsivities. If $C_A \gg C_E$ the voltage response is proportional to:

$$F_i = \frac{p}{c'} \quad (7)$$

Eq. (7) gives another material FOM. Therefore the choice of the appropriate material will depend both on the amplifier to be used (e.g., JFET have higher input capacitances than MOSFET) and on the size of the detector element. Small area detector elements tend to favor high dielectric constant materials and vice versa to produce a good match between C_A and C_E . If there are a number of elements or detector points defined on a single plate of material, lateral thermal diffusion in the plate will tend to "smear-out" high spatial frequency information. In this case, it would be appropriate to introduce the thermal diffusivity (κ) in the denominator of these FOM, so that lower diffusivity materials will be favored. However, the introduction of technologies (e.g., "reticulation") to physically disconnect adjacent elements would eliminate this need.

It is evidently insufficient to consider only the response of a detector when analyzing its usefulness for a particular application. It is generally necessary to analyze both intrinsic and extrinsic noise signals and compare them with the response. Johnson noise generated by the dielectric loss of the detector material is usually the most important source of electrical noise in the important frequency ranges from 1 to 100 Hz, if the amplifier noise sources are minimized. The total electrical conductance g (consisting of the parallel conductances of gate bias resistor R_G and the AC conductance of the detector element g_D) gives rise to the Johnson noise. It can be shown that for frequencies much less than ω_G , where $\omega_G = (R_G C_E \tan \delta)^{-1}$ ΔV_J is given by:

$$\Delta V_J = \sqrt{\frac{4kTR_G}{1 + \omega^2 \tau_E^2}} \quad (8)$$

(where k is Boltzmann's constant). This leads to an ω^{-1} dependence at frequencies $\omega \gg \tau_E^{-1}$. For frequencies greater than τ_E^{-1} and ω_G the Johnson noise generated by the AC conductance of the detector element frequently dominates in pyroelectric detectors so that the specific detectivity of the detector (D^*) is given by:

$$D^* = R_V \frac{\sqrt{A}}{\Delta V_J} = \frac{\eta d}{\sqrt{4kT}} \times \frac{p}{c' \sqrt{\epsilon \epsilon_o \tan \delta}} \times \frac{1}{\sqrt{\omega}} \quad (9)$$

Thus to maximize D^* in the region where Johnson noise dominates, it is desirable to maximize:

$$F_D = \frac{p}{c' \sqrt{\epsilon \epsilon_o \tan \delta}} \quad (10)$$

which forms the third FOM for pyroelectric materials. (This is frequently expressed in units of $\mu\text{Pa}^{-1/2}$.)

Pyroelectric Material Selection

As noted in the introduction, all polar dielectric materials show the pyroelectric effect, which implies that there is potentially a huge range of materials to choose from for devices. The material FOMs F_V , F_i , and F_D derived in the previous section serve as a useful guide for selecting a particular material for a given application. If the detector element and amplifier have well-matched capacitances and the amplifier noise has been minimized, then the device noise will be dominated by the Johnson noise generated by the dielectric loss in the element. In this case, maximizing F_D will maximize the detectivity. If one of the other noise sources is dominant or if the capacitance of the element dominates the input capacitance of the amplifier, then maximizing F_V will maximize the detectivity. On the other hand, if the capacitance of the element is small in comparison with that of the input capacitance of the amplifier, and the noise sources other than that due to the dielectric loss of the element are dominant, then maximizing F_i will maximize the detectivity.

In certain types of devices, the physical design of the detector element is constrained by the application and/or fabrication technologies, which can have an effect on the selection of materials. For example, in solid-state thermal imaging arrays, it is necessary to put a certain number of detector elements into an area that is at the focus of a lens (typically made of germanium), which will image the scene at the wavelength of interest. This means attaching a plate of the pyroelectric material to a silicon chip, which carries an array of MOSFET amplifiers and switches designed to read out the pyroelectric signals. The size of such electronic chips is limited (typically to 1 or 2 cm across), which in turn limits the maximum area of the detector elements. (A typical example would be an array of 80 μm square elements on a 100 μm pitch in a 100 $\times$ 100 imaging array.) In a well-matched detector, we would like the element capacitance to be of the same order as the amplifier input capacitance, which will typically be about 1 pF. It is thus important, if performance is to be optimized, to select a material that possesses a dielectric constant that will give a good capacitance match for a given element thickness, d . The thickness is determined by two considerations, one theoretical and one practical. Intuitively, it might be thought best to minimize the element thickness (and therefore its thermal capacity H) to maximize the temperature change for a given energy input. However, it is necessary to consider the balance between H and the thermal conductance G_T at the required operating frequency of the device. For practical reasons, it may not be possible to reduce G_T below a certain value. A practical value for a particular design of array might be perhaps 10–20 $\mu\text{W K}^{-1}$. If the device is to operate at ca 50 Hz, then a thermal time constant of 20 ms for the device would be appropriate. It is then simple to show that for our example of an 80 μm square element with a volume-specific heat of 2.5 $\text{MJ m}^{-3}\text{K}^{-1}$, the element thickness must be around 25 μm . Hence, for a C_E of 1 pF, the permittivity of the material should be around 440. A smaller element (say 40 $\times$ 40 μm) will require a material with an even higher permittivity (ca. 1000), unless the thermal conductance can be lowered by an improvement in the thermal isolation technology. Thus choosing a material with a higher F_D for this application may not necessarily give better performance than another material with a lower F_D if its permittivity is much lower than this value. The second consideration determining element thickness is technological. Many of the best pyroelectric materials are oxides, which are brittle and have a tendency to break during handling when in very thin sections. Hence, if a bulk ceramic material is used, then the minimum attainable thickness (say 15–20 μm) may push the selection of a material toward one with a higher dielectric constant. On the other hand, technologies are now emerging (see below) by which thin films of ferroelectric materials can be deposited directly onto active silicon chips while maintaining good thermal isolation. In such cases, the thickness of the detector element can be very thin indeed ($< 1 \mu\text{m}$) and it may be more advantageous to choose a material with a moderate dielectric constant.

This simple example serves to show that, while the FOM listed above can be useful in guiding one in the right general direction for selecting a material, it is essential to consider the full details of any device's operation and manufacturing technology in choosing the most appropriate material to use.

A further consideration in the selection of materials is the frequency dependence of the dielectric properties. The vast majority of pyroelectric devices operate at very low frequencies (usually < 100 Hz, frequently < 10 Hz). Most of the so-called "low-frequency" dielectric properties reported in the literature have been measured at 1 kHz or above. For many materials, the loss tangent rises rapidly as the frequency decreases in the range 100–0.1 Hz. This means that pyroelectric FOM based on dielectric data measured in the range of 1 kHz may be of use in cross-comparing values of F_V but are of questionable utility in comparing values of F_D as the low-frequency dependences of the dielectric losses of the different materials may differ.

It was noted in the introduction that ferroelectrics show the largest pyroelectric coefficients by virtue of the changes in their spontaneous polarizations with temperature as the temperature increases toward the Curie temperature, T_C . This leads to a maximum in the pyroelectric coefficient at T_C . The dielectric constant in a proper ferroelectric also increases and peaks at T_C . It is possible to show from Devonshire theory (Lines and Glass, 1977) that in a proper ferroelectric in the absence of an electric bias field the ratio $p/\sqrt{\epsilon}$, and hence the detectivity at constant $\tan\delta$, are constant below T_C , meaning that the devices require little-or-no thermal stabilization to maintain a stable performance.

The major compromise as the temperature approaches T_C is an increase in dielectric loss due to an increased facility of domain wall movement, which tends to reduce F_D , and a tendency to depole the ferroelectric, giving a general loss in activity (especially for ceramics). This means that most ferroelectrics are operated well below their T_C . However, if an electric bias field is applied to the ferroelectric, the polarization and the pyroelectric effect will be stabilized in the region of and above T_C . It is also observed that the dielectric constant tends to reduce, as does the dielectric loss as the domain walls are effectively "swept out" of the material by the field. The consequence of this is that very large pyroelectric coefficients in conjunction with large dielectric constants and low dielectric losses can be measured in the region of T_C . This is the principle of the "dielectric bolometer" by which the pyroelectric coefficient is given by:

$$p = \left(\frac{dD}{dT} \right)_E \quad (11)$$

The following discussion separates pyroelectric materials into two groups: “intrinsic” pyroelectrics, which are operated well below T_C ; dielectric bolometer materials, which are operated close to T_C ; but with an electrical bias applied and ferroelectric thin films.

Bulk Pyroelectric Materials

Intrinsic Pyroelectrics

The reviews by [Whatmore \(1986\)](#) and [Kulwicki et al. \(1992\)](#) have considered in detail the properties of many of the “intrinsic” bulk (as opposed to thin film) pyroelectric materials. There are many different types of pyroelectrics, including single crystals, polymers, and ceramics. The triglycine sulphate (TGS) family was one of the earliest materials to be used for single-element detectors. Many modifications to this compound have been developed, including the deuterated isomorph deuterated triglycine sulphate (DTGS) in which deuteration is used to raise T_C ; the replacement of some of the glycine groups by alanine, which serves to stabilize P_S above T_C ; and the replacement of the sulphate groups by, for example, fluoroberyllic acid deuterated triglycine fluoroberyllate (DTGFB). The room-temperature properties of TGS and DTGS are listed in [Table 1](#).

The materials are water-soluble and can be grown as large single crystals from aqueous solution. They possess relatively low dielectric constants and exhibit very high F_V values, which means that they are still used in high-performance single-element detectors, such as for spectroscopic analysis. Outside this area, their water solubility and low Curie temperatures means that their use is confined to the pyroelectric vidicon (see, e.g., [Putley et al., 1972](#)). Here, their low thermal diffusivities are advantageous. Lithium tantalate is an example of an oxide single crystal that is widely used in commercial single-element detectors because of its relatively good pyroelectric properties – especially F_V (see [Table 1](#)), high T_C , good chemical stability, ready commercial availability, and ease of handling. Its properties are not particularly favorable for use in thermal imaging arrays because of its low permittivity. The thermal diffusivities perpendicular to the polar axis are quite high, which can lead to issues of thermal crosstalk between adjacent elements of detector arrays at low modulation frequencies, if the array element size is small. Many other oxide single crystal materials have been studied for their use in pyroelectric applications. The tungsten bronze family has been of considerable interest, as the pyroelectric coefficients obtained are high. $\text{Sr}_{0.5}\text{Ba}_{0.5}\text{Nb}_2\text{O}_6$ was of particular interest with a pyroelectric coefficient more than three times that of LiTaO_3 and double that of DTGS, with high permittivities, making them potentially of interest for arrays of small detectors. However, the crystals are hard to grow in large sizes, are not readily available commercially, and have relatively low Curie temperatures, so the user must be careful not to accidentally depole the devices using them by allowing them to get too hot. New ferroelectric crystals based on the solid solutions.

$x\text{PbMg}_{1/3}\text{Nb}_{2/3}\text{O}_3-(1-x)\text{PbTiO}_3$ (PMNT) have been extensively studied over the last few years because of their excellent piezoelectric properties and potential applications in medical ultrasound and sonar systems ([Park and Shrout, 1997](#)). The pyroelectric properties of some of these have been studied. [Table 1](#) shows the properties of a crystal with $x = 0.74$ (PMNT(74/26)) and an example of a ternary solid solution crystal containing lead indium niobate (PIMNT(21/49/30)). These crystals are rhombohedral at room temperature and exhibit a transition to a ferroelectric, tetragonal phase before they become paraelectric (and depole completely). This transition means that crystals need to be repoled if the R–T transition temperature (T_{R-T}) is exceeded, which is inconvenient. The crystals containing lead indium niobate have significantly higher values of T_{R-T} and thus may be more useful. Nevertheless, the pyroelectric coefficients of these materials are very high, and the values of F_D some of the highest in non-TGS oxide-based systems, being comparable with LiTaO_3 . They also have the advantage of being materials that are commercially available, being grown for the piezoelectric application.

The ferroelectric polymers polyvinylidene fluoride (PVDF) and the vinylidene fluoride–trifluoroethylene (P(VDF/TrFE)) copolymers exhibit ferroelectric behavior and interesting pyroelectric effects. PVDF is commercially available as poled and electroded polymer sheets of varying thicknesses. PVDF needs to be mechanically stretched before poling to develop its ferroelectric properties. The P(VDF/TrFE) copolymers, however, can be cast from the melt or methyl ethyl ketone solution directly into the ferroelectric phase. They are thus particularly interesting for pyroelectric applications in which a film of pyroelectric is deposited directly onto a silicon substrate for making arrays. The properties of PVDF and a P(70VDF/30TrFE) polymer are illustrated in [Table 1](#). These properties are typical of those that can be achieved in this system. These are characterized by low pyroelectric coefficients and low dielectric constants coupled with moderate dielectric losses. As a consequence, the F_V values are similar to those of LiTaO_3 , but the F_D values are much lower. The low dielectric constants of these materials make them relatively unfavorable for large arrays of very small ($<100\ \mu\text{m}$ square) detectors for the thermal imaging applications, although thin-film detectors with areas around this value have been made on micromachined silicon ([Setiadi et al., 1996](#); [Kohler et al., 1998](#)).

Many ceramic ferroelectrics has been explored for their possible applications in pyroelectric devices and a large proportion of these are based upon the lead zirconate–lead titanate ($\{1-x\}\text{PbZrO}_3-x\text{PbTiO}_3$ –PZT) perovskite solid solution series. The compositions of greatest interest are located either close to the lead zirconate end of the phase diagram or close to lead titanate. The dielectric constants and losses of these compositions are lower than the corresponding values close to those at the morphotropic phase boundary at $x = 0.47$, which are commonly used for piezoelectric device applications. Pyroelectric properties typical of these types of materials (referred to as Mod PZ and Mod PT, respectively) are listed in [Table 1](#). The materials are characterized by

high dielectric constants (typically ca. 200–300), and low, but strongly frequency dependent, dielectric losses. The FOM (especially F_D) for these materials look good if the 1k Hz dielectric properties are taken (conducting a straight comparison with the other materials in Table 1) and the high dielectric constants of these materials make them very suitable for use in arrays of small detectors.

For these materials, it has been possible to quote the dielectric properties at 1 kHz and 33 Hz to illustrate the differences in FOM (especially F_D), which are obtained by going to the frequency range of interest for device applications. The F_D figures are reduced by around a factor of two. However, low-frequency dielectric loss data for many materials is hard to obtain from the literature, and therefore a direct comparison of the materials at the most relevant frequency range is not possible. This illustrates the difficulty of making valid materials comparisons simply on the basis of available data. Many studies of pyroelectric materials either fail to report the frequency at which measurements have been carried out, or specify a frequency for the dielectric measurements, which is well outside the range of interest for most devices.

Dielectric Bolometer Materials

It was noted above that, by operating a proper ferroelectric close to T_C with an electric bias field applied, very high effective pyroelectric coefficients can be obtained. Several materials have been examined in this mode, including $\text{KTa}_x\text{Nb}_{1-x}\text{O}_3$ (KTN) (Stafsud and Pines, 1971); $\text{Pb}(\text{Zn}_{1/3}\text{Nb}_{2/3})\text{O}_3$ (PZN) (Yokomizo *et al.*, 1970); $\text{Ba}_x\text{Sr}_{1-x}\text{TiO}_3$ (BST) (Whatmore *et al.*, 1987; Kulwicki *et al.*, 1992); $(\text{Pb}_{0.99}\text{La}_{0.01})(\text{Mg}_{1/3}\text{Nb}_{2/3})\text{O}_3$ (La01-PMN) (Whatmore *et al.*, 1987); and $\text{PbSc}_{1/2}\text{Ta}_{1/2}\text{O}_3$ (PST) (Shorrock *et al.*, 1990). In characterizing these materials, it is necessary to measure their properties over a wide range of fields and temperatures. A typical set of properties in a BST67/33 ceramic at $0.6 \text{ V } \mu\text{m}^{-1}$ bias field is $p = 70 \times 10^{-4} \text{ cm}^{-2} \text{ K}^{-1}$, $\epsilon = 8800$ and $\tan\delta = 0.004$, giving $F_D = 124 \text{ } \mu\text{Pa}^{-1/2}$ (Kulwicki *et al.*, 1992). The field and temperature dependence of the relevant properties of BST65/35 and La01PMN ceramics have been reported by Whatmore *et al.* (1990) and for PST by Shorrock *et al.* (1990). In PST the p and ϵ are strongly peaked with temperature at low bias fields, but the peaks become lower and broader and shifted to higher temperatures at high bias fields. The effect of field on dielectric loss is to dramatically reduce it immediately below T_C and to increase it slightly above.

At low bias fields, the temperature dependence of the response and signal-to-noise FOM of dielectric bolometer materials is strongly temperature dependent in the region of T_C , as would be expected. Kulwicki *et al.* (1992) showed that in BST67/33, a second-order ferroelectric, the F_D peaks at $140 \text{ } \mu\text{Pa}^{-1/2}$ at 22°C and $0.4 \text{ V } \mu\text{m}^{-1}$ bias field. Within $\pm 2^\circ\text{C}$ from this temperature, the value falls to about one half of this figure. F_V varies similarly. This seems to make tight control of device temperature essential. However, application of higher bias fields allows this requirement to be relaxed. In PST ceramics at $5 \text{ V } \mu\text{m}^{-1}$ bias there is a much slower temperature variation, with a peak at 40°C , which is about $150 \text{ } \mu\text{Pa}^{-1/2}$. Some temperature stabilization would still be required to optimize the performance of the device, but this is not tight and could, for many applications, be achieved by heating alone, eliminating the need for a thermoelectric cooler.

Devices

Pyroelectric IR detectors containing one or two sensitive elements are used in a wide range of applications, including intruder sensing, remote light switches, spectroscopic gas analysis, flame and fire detection equipment, etc., as described by Porter (1981). Such devices typically employ LiTaO_3 single crystal or PZT-based ceramic elements at the low-cost end. The highest performance pyroelectric single- or few element devices used in Fourier Transform Infra-Red spectroscopy still typically use TGS-based single crystal materials. Linear arrays of up to 256 elements using LiTaO_3 single crystal materials for use in spectroscopy applications have been described by Norkus (2004).

Hybrid 2D arrays with a typical structure as shown in Fig. 2 have been fabricated using the Mod PZ, PST, and BST ceramics referred to in the previous section (Watton *et al.*, 1993; Kulwicki *et al.*, 1992). The ferroelectric wafer, 10–25 μm thick, is cut and polished from a hot-pressed ceramic block and has a common electrode on its top surface, which forms part of a matched thin film ($\lambda/4$) structure for radiation absorption. The rear surface has a pattern of individual element electrodes for bonding. A maximized signal is obtained by minimizing the heat loss from the individual element through three design features: The small diameter of the solder bond, typically 10 μm ; isolating the bond from the silicon read-out IC by a thick polymer layer and a narrow metal interconnection track; and isolating the detector element from its neighbors by laser etching grooves into the ceramic (reticulation). Without reticulation, heat would spread laterally between the elements, reducing the image resolution. Arrays with numbers of elements up to 388×256 have been made with an element pitch from 100 μm down to 40 μm , and groove widths are from 20 μm down to 10 μm . Noise-equivalent temperature differences in the image are typically of the order of 0.1K. Such arrays can be used for forming thermal images using radiation in the 8–14 μm band, with the array of elements placed at the focus of a germanium lens. Applications for such systems include both military and commercial areas. Publication of military use has been limited, but equipment for a Driver's Vision Enhancer and a Thermal Weapon Sight have been described (Hanson *et al.*, 1992). A major civil area, that of firefighting cameras, has been pursued by Cairns & Brother Inc., who manufactured a helmet-mounted uncooled camera based on GEC-Marconi array modules (Bennett and Matthews, 1996). Other civilian applications have included police patrol car surveillance cameras, civilian automotive driving aids, and general-purpose thermal imaging for industrial and security monitoring. The major competition for ferroelectric ceramic-based thermal imaging has come from resistance bolometer

Fig. 2 Hybrid array structure using bulk pyroelectric material.

arrays using micromachined elements made from the thin films of VO_x or amorphous silicon (Niklaus *et al.*, 2008). The technology for making these lends itself to lower-cost, MEMS-based production techniques and arrays of up to 640×480 and larger with element pitches below $20 \mu\text{m}$ are now commercially available. These have displaced the hybrid ferroelectric ceramic arrays in the high-resolution thermal imaging application. However, pyroelectric hybrid arrays have certain advantages. The resistance bolometer arrays require vacuum encapsulation, which can be an expensive technology. The hybrid pyroelectric arrays do not need this. A further key advantage of the pyroelectric array is that it responds to changes in temperature, while a resistance bolometer array responds to absolute temperature. This means that a pyroelectric array placed at the image plane of a germanium lens will only see changes in the thermal image of the scene. In situations where warm objects such as people moving in a scene (perhaps for security or people-counting applications) need to be seen, rather than seeing the full thermal image, pyroelectrics are ideal because they require very little signal processing to achieve this. Low element count (e.g., 16×16 or 32×32) arrays have been very successful for applications such as fall detection in older populations (Sixsmith *et al.*, 2005) and queue-length monitoring, as well as low-cost thermal imaging (Holden, 2011).

Pyroelectric Thin Films

The use of bulk ferroelectrics in pyroelectric devices inevitably leads to situations where the material must be cut, lapped, and polished to make a thin, thermally sensitive layer. If an array of detectors is required for thermal imaging, the layer must be metallized on both faces, processed photolithographically, and bonded to a silicon read-out circuit to yield a complete hybrid array. Clearly, it would be desirable if the ferroelectric material could be deposited as a thin film onto a substrate, which would be chemically etched to leave a free-standing ferroelectric thin film, minimally supported to reduce thermal conduction from the ferroelectric to its surroundings, and thus removing the requirement for lapping and polishing. If possible, the thin film would be deposited directly onto a complete wafer of silicon chips, where it could be processed to yield an array of thin, thermally isolated structures. This requirement places a very important constraint on the temperature at which the ferroelectric is grown. The silicon circuits required for thermal imaging are complex very large scale integration (VLSI) chips, which are manufactured in silicon foundries in wafers of 6" diameter or more. It is unlikely that a general silicon foundry could accept for deposition the sorts of exotic materials discussed in the previous sections. Hence, the ferroelectric layer must be deposited on fully processed and tested wafers. However, the interconnect metallization on the chips should not be taken above about $450\text{--}500^\circ\text{C}$ for any length of time and this places an upper limit on the ferroelectric layer process temperature. The ferroelectric copolymers discussed above are interesting for this application, as they can be spun-down and cast directly onto the silicon at room temperature. These require only an anneal at ca. 150°C to develop full crystallinity. Pyroelectric arrays using P(VDF-TrFE) thin films directly deposited onto silicon have been demonstrated (Vonnunich *et al.*, 1993; Kohler *et al.*, 1998). However, it can be seen from Table 1 that the pyroelectric properties of the ferroelectric polymers are not as good as the oxide materials (modified lead zirconate titanates or the dielectric bolometer materials), which were discussed in the previous two sections. In particular, the oxides possess better properties for large arrays of small detectors (high dielectric constants and high values of F_D), but they are normally manufactured as ceramics for which the sintering temperatures are around 1200°C . Fortunately, many techniques have been researched for ferroelectric thin-film deposition, mainly for applications to nonvolatile memories (Scott and de Araujo, 1989). These include chemical solution deposition (CSD) – particularly sol-gel or metal-organic deposition (MOD), radio frequency (RF) magnetron sputtering, pulsed laser ablation deposition (PLD), and metal-organic chemical vapor deposition (MOCVD). These methods have all been well reviewed by de Araujo *et al.* (1996) and each has its own advantages and disadvantages. CSD processes tend to be relatively low cost to set up and simple to apply, with the capability for easy compositional modification, but being wet chemical processes are perhaps less acceptable in a semiconductor device processing context; sputtering and MOCVD are capital intensive processes and difficult to modify for complex film compositions, but are standard in the semiconductor industry and capable of

coating onto large-area substrates, PLD is best-suited to small-area substrates but has the advantage of being able to deposit films with complex compositions relatively quickly, as there is good correspondence between the target and the film compositions. Commercial PLD deposition systems suitable for large-area growth are becoming available.

Intrinsic Pyroelectrics

Table 2 summarizes the properties as reported recently in the literature of modified PZT thin films deposited onto Pt/Ti on Si substrates where deposition has been at temperatures below 700°C. The best F_D values are in the range 10–35 $\mu\text{Pa}^{-1/2}$ and are comparable with the properties reported for bulk ceramic pyroelectric materials. The lowest deposition temperatures reported to date have been with compositions in the PZT30/70 region. Modification of the films by doping with Mn or Nb has been shown to give significant improvements to the FOM. It has been shown that sol–gel processing can give excellent properties for films grown at 530°C or below. It can be seen from **Table 2** that RF magnetron sputtering has been used successfully to produce good-quality PZT25/75 films at nominal substrate temperatures of 450°C, although it should be noted that it is hard to get an accurate measurement of real substrate temperatures in sputtering systems because the monitoring thermocouples are usually quite remote from the substrate, which is also subject to heating from the plasma. Hence, the real growth temperature can be significantly higher than that recorded. MOCVD has not yet been used to produce such good films at temperatures below 535°C, mainly because of the problem of finding metal–organic precursors for all the constituent atoms, which will decompose at an appropriate rate at such low temperatures.

The best films on Pt/Ti/Si substrates are all polycrystalline, but tend to be strongly (111) orientated. At first sight, this may seem to be surprising, as the compositions are all tetragonal, with the polar axis along (001). However, it is found that if films are deposited with the cubic axes of the crystallites normal to the substrate plane, the tensile stresses in the film tend to force the polar axis to be in the substrate plane, reducing the net polarization and pyroelectric coefficient. Workers using other substrate systems have been able to make films with (001) normal to the film plane. For example, [Fujii et al. \(1994\)](#) have deposited $\text{Pb}_{0.9}\text{La}_{0.1}\text{TiO}_3$ at 590°C by RF magnetron sputtering epitaxially onto (100) single-crystal MgO substrates. They obtained $p = 500 \mu\text{cm}^{-2}\text{K}^{-1}$ and $F_D = 51 \mu\text{Pa}^{-1/2}$. The growth of perovskite films onto substrates other than silicon will clearly require a technology for removal of the film from the substrate and its interfacing with amplifier/multiplexer circuitry. [Fujii et al. \(1994\)](#) etched the back face of the MgO crystal substrates to locally release a portion of the films, which was electrode and patterned into individual elements prior to film release. This has been used to make linear arrays with $D^* = 3.5 \times 10^8 \text{ cm Hz}^{1/2} \text{ W}^{-1}$ at 20 Hz.

Dielectric Bolometers

As discussed above, there can be great benefits gained in pyroelectric properties, especially for thermal imaging devices, by using a ferroelectric close to T_C under an applied bias field. This has led to a drive to grow thin films of such materials. Lead scandium tantalate (PST) has been a prime candidate for such work. Complex perovskites such as this tend to be harder to crystallize into the perovskite phase than members of the PZT system close to lead titanate. There have been some extremely promising properties produced from films crystallized at relatively high temperatures on a variety of substrates. [Shorrock et al. \(1992\)](#) showed that 4 μm thick films of PST can be grown onto sapphire substrates with a 1 μm MgO coating and crystallized at 900°C. These were subsequently released by dissolution of the MgO layer in phosphoric acid to give films with $p > 2500 \mu\text{cm}^{-2}\text{K}^{-1}$, $\epsilon = 2500$, and F_D up to 110 $\mu\text{Pa}^{-1/2}$ at 4.2 $\text{V } \mu\text{m}^{-1}$ bias field. [Watton and Todd \(1991\)](#) also demonstrated PST films on sapphire substrates annealed at 900°C to yield $p \cong 5000 \mu\text{cm}^{-2}\text{K}^{-1}$, $\epsilon = 5800$, and $F_D \cong 110 \mu\text{Pa}^{-1/2}$. [Cho et al. \(1995\)](#) have demonstrated 0.85{Pb($\text{Mg}_{1/3}\text{Nb}_{2/3}$)O₃} – 0.15{Pb($\text{Zn}_{1/3}\text{Nb}_{2/3}$)O₃} films on (111)Pt-on-(100)MgO substrates. These exhibited $p \cong 150 \mu\text{cm}^{-2}\text{K}^{-1}$, $\epsilon = 1150$, and $F_D \cong 31 \mu\text{Pa}^{-1/2}$ at 3 $\text{V } \mu\text{m}^{-1}$ bias after annealing at 900°C. [Mantese et al. \(1993\)](#) produced films of $\text{KTa}_{1-x}\text{Nb}_x\text{O}_3$ on yttria substrates using a MOD method, and after annealing at 1070°C, the films exhibited $p \cong 150 \mu\text{cm}^{-2}\text{K}^{-1}$ at 3 $\text{V } \mu\text{m}^{-1}$ bias. 10 μm thick films were separated from the substrates by etching and fabricated into working arrays. However, excellent though these pyroelectric properties are (and all at around 15–25°C), the films all require removal from the substrate and hybridization with a readout chip to make a working device. Thus there has been a strong drive to reduce the firing temperature to ca. 500°C so that a process fully integrated with silicon can be devised. [Watton \(1995\)](#) reported that if PST is sputtered with a large Pb excess (14%–37%), the perovskite phase can be induced to grow on Pt/Ti/Si substrates at 525–575°C, and the films possessed $p \cong 440 \mu\text{cm}^{-2}\text{K}^{-1}$, $\epsilon = 650$ –850, and F_D up to 30 $\mu\text{Pa}^{-1/2}$ at 10–15 $\text{V } \mu\text{m}^{-1}$ bias, well below the values reported for films deposited at high temperature, but still useful.

In conclusion, pyroelectric thin films can certainly be deposited directly onto silicon substrates at temperatures below 500°C and F_D values of between 10 and 35 $\mu\text{Pa}^{-1/2}$ seem to be reliably achievable using a variety of growth techniques. There may be some gains to be had in F_D (up to $> 100 \mu\text{Pa}^{-1/2}$) by using a dielectric bolometer material such as PST if a higher growth temperature can be tolerated (i.e., if the film is not to be grown onto active silicon). A hybrid process whereby the film is grown onto a separate substrate prior to linking with an active silicon circuit has been described as one way to achieve this ([Todd et al., 2000](#)).

Devices

A number of pyroelectric device structures using directly deposited thin films have been demonstrated. These include linear arrays of 128 elements with an area of $90 \times 100 \mu\text{m}^2$ and 2D arrays with 16×8 elements $400 \times 400 \mu\text{m}^2$ ([Kohler et al., 1998](#)), which

Fig. 3 Micromachined array structure using thin film pyroelectric material.

Fig. 4 Schematic of an integrated detector element employing a surface micromachined microbridge structure for good thermal isolation.

were made using both spin-coated and annealed P(VDF75-TrFE25) copolymer and sputtered PZT25/75. These were made on silicon substrates, but the silicon contained no active elements and was used as a carrier substrate that could be bulk micro-machined to release the pyroelectric elements, giving a structure of the type shown schematically in [Fig. 3](#).

For 1 mm² sensor elements, the PZT detectors showed a detectivity that was ca. $5 \times$ greater than the polymer detectors, reflecting the much higher pyroelectric coefficient and F_r of the oxide material (see [Tables 1](#) and [2](#)). It is interesting that FV and FD are similar for the two materials, which reflects the importance of selecting the appropriate FOM when comparing the likely performance of different materials in a particular sensor design. [Kohli et al., 1998](#) reported the fabrication and properties of linear arrays of 12 elements with 0.36 mm² area using sol-gel grown PZT15/85. It is interesting to note that in both of these examples, the best values of D^* obtained from the PZT detectors were very similar at $\approx 2 \times 10^8$ cm Hz^{1/2} W⁻¹. Pyreos Ltd. in the UK have commercialized pyroelectric devices based on sputtered PZT25/75 on bulk micromachined silicon and [Wojtczuk et al. \(2011\)](#) have demonstrated hand-gesture sensors using a 4×4 array from this manufacturer.

It is also possible to make integrated thin-film pyroelectric arrays using surface micromachined structures. These are advantageous because they can be manufactured with processes of the type used for making silicon-integrated circuits, without having to access the rear surface of the wafer for “back-side” etching. In principle, such structures also permit the use of the full area of the silicon for active circuitry, such as gate amplifiers and multiplexers. A typical structure for arrays with thin ferroelectric films is shown in [Fig. 4](#). The microbridge legs illustrated can provide much better thermal isolation of the element than the solder bonds of hybrid arrays shown in [Fig. 2](#). Thermal conductance through the legs can be made as low as 1–0.1 μ W/K, an improvement over the solder bond by one-to-two orders of magnitude. A disadvantage of such structures is that gas within the narrow gap beneath the active element can provide a major source of thermal leakage and thus the package must be either filled with a low thermal conductivity gas, such as xenon, or ideally evacuated to remove these effects. If radiation absorption in the microbridge itself is used, then the ferroelectric film must be ~ 1 μ m thick ($\lambda/4$ at 10 μ m). The improvement in thermal isolation achievable by integration when compared with hybrid arrays should allow some relaxation in the requirements for the ferroelectric film FOM. For example, F_D values of 20 to 30 μ Pa^{-1/2} should allow NETDs of 100 mK and below. [Todd et al. \(2000\)](#) reported that engineers at BAE Systems successfully demonstrated 256×128 arrays made with thin films of PZT30/70, as described by [Shorrocks et al. \(1995\)](#), possessing $F_D \approx 16$ μ Pa^{-1/2}. The elements showed a mode NETD of 140 mK, even before poling, in good agreement with predictions.

Superconducting Materials

Peter Majewski, University of South Australia, Adelaide, Australia

Introduction

In 1911 the Dutch physicist [Onnes \(1911\)](#) observed during studies of the electric properties of pure metals at temperatures near absolute zero (0K or -273.15°C), that the resistance of a mercury wire dropped precipitously when cooled to below 4.2K (-268.95°C). He soon recognized this to be the manifestation of a new state of matter “which on account of its extraordinary electrical properties may be called the superconducting state.”

For over 20 years after the discovery of superconductivity, this new state was believed to be just an ideal conductor that loses its resistance below a distinct temperature, the so-called critical temperature, T_c . In the year 1933, [Meissner and Ochsenfeld \(1933\)](#) discovered that magnetic fields are excluded from the inside of a superconductor even on cooling in a constant magnetic field that could not be explained by classical electrodynamics. This effect is known today as the Meissner–Ochsenfeld effect.

Bardeen *et al.* published their comprehensive theory of superconductivity in 1957 ([Bardeen *et al.*, 1957](#)). The salient point of the so-called BCS theory is the attractive electron interaction mediated by phonons. By that virtue, two electrons couple to form so-called Cooper pairs, which act in a fundamentally different way from single electrons. Being quasi-particles with integer spin, Cooper pairs follow the Bose–Einstein statistics which allows them to condense into a single quantum mechanical state, with all Cooper pairs having the same wave function. Thus, superconductivity is often referred to as a macroscopic quantum phenomenon ([Matthias *et al.*, 1965](#)). The BCS theory was very successful in predicting the critical temperature of a material and provided an explanation for the isotope effect, according to which the critical temperature shifts as a function of the isotopic mass of chemical elements.

With the discovery of materials showing transition temperatures near and above 100K, it became evident that the BCS theory would not be adequate to describe this new class of superconductors, known as high-temperature superconductors, in contrast to the term “low-temperature superconductor” which comprises all superconductors with critical temperatures below about 30K. Experiments gave evidence that the charge carriers of superconductivity are Cooper pairs. But, the question about the nature of the force that keeps the Cooper pairs together is still a matter of investigation.

Since the first observation of superconductivity in mercury, thousands of compounds and alloys were investigated with respect to their superconducting properties ([Tinkham, 1975](#)). In [Fig. 1](#) the fever curve of superconductivity is shown, which is marked by the highest critical temperature known during that time. Since 1993, several new superconductors have been found. None of them, however, have surpassed the world champion $\text{HgBa}_2\text{Ca}_2\text{Cu}_3\text{O}_8$ exhibiting a T_c of 138K at ambient pressure, and 164K at an isostatic pressure of 23 GPa.

Type 1 Superconductors

Type 1 superconductors – also known as the “soft” superconductors – are characterized by a very sharp transition to a superconducting state at T_c , and by “perfect” Meissner–Ochsenfeld effect up to the so-called critical field, B_c . Above T_c the material becomes normal conducting. Even here, the transition is very sharp ([Fig. 2](#)). The value of B_c is temperature dependent and reaches zero at T_c . However, the magnetic field is not repelled at the surface of the superconductor, but penetrates it within a 10^{-8} – 10^{-7} m thick surface layer causing screening electric currents in the surface layer. These currents generate a magnetic field which is anti-polarized to the external field. This phenomenon is the reason for the well-known levitation effect of a permanent magnet above a superconductor, or vice versa.

Fig. 1 Maximum critical temperature vs. time.

Fig. 2 Magnetization of a Type 1 superconductor vs. the external field, B_{ex} . Insert: Magnetic field within a Type 1 superconductor, B_{in} , vs. the external field, B_{ex} .

Fig. 3 Magnetization of a Type 2 superconductor vs. the external field, B_{ex} . Insert: Magnetic field within a Type 2 superconductor, B_{in} , vs. the external field, B_{ex} .

The so-called penetration depth, λ , of the external magnetic field is a material property. It also is temperature dependent and increases asymptotically towards T_c . At the particular field B_c relatively thick normal and superconducting domains running parallel to the field can coexist, known as the intermediate state.

Type 2 Superconductors

Type 2 superconductors – also known as the “hard” superconductors – differ from Type 1 in that their transition from a normal to a superconducting state is gradual across a region of “mixed state” behavior. A Type 2 superconductor exhibits a very different behavior in an external magnetic field compared to the Type 1 superconductors. At low external fields, like the Type 1 superconductor it repels the magnetic field up to the lower critical field, B_{c1} . This region is also called the “Meissner phase.” Above B_{c1} , regularly divided quantified flux vortices or flux lines enter the material up to the so-called upper critical field, B_{c2} (Fig. 3). In the region between B_{c1} and B_{c2} , superconducting and nonsuperconducting areas with trapped magnetic flux lines are present (Fig. 4). With increasing magnetic fields, the trapped flux lines move closer together and more trapped flux lines occur, so that the superconducting volume decreases and that of the nonsuperconducting increases. The region is called the “Shubnikov phase” or the mixed state. The values of B_{c1} and B_{c2} are also temperature dependent and decrease with increasing temperature. At T_c both values, B_{c1} and B_{c2} , are zero (Fig. 5).

Fig. 4 Type 2 superconductor with trapped flux lines vortex.

Fig. 5 Lower and upper critical field of a Type 2 superconductor vs. the temperature.

Critical Current Density

Both categories of superconductors, Types 1 and 2, can carry large electric currents up to a certain value which is called the critical current density, J_c (A cm^{-2}). Above J_c , the superconductor becomes normal conducting. J_c is dependent on both the temperature and the external magnetic field. At T_c or B_c (Type 1) or B_{c2} (Type 2) the value of J_c is zero and the superconductor becomes normal conducting (Fig. 6). Superconductors show characteristic current versus voltage behavior. At a current below J_c the voltage is zero. Above J_c , as in a metal, the voltage increases with the current (Fig. 7).

In the mixed state, when an electric current is transported through the superconductor due to the Lorentz force, the trapped flux lines can move through the superconductor causing dissipation of the current and a warming of the superconductor. This phenomenon can result in a rapid transition into the normal conducting state. Therefore, the value of J_c is significantly lower in the Shubnikov phase compared to the Meissner phase. However, the flux lines can be pinned by so-called pinning centers, which are defects with different dimensions within the superconductor. For example, point defects (zero dimension), dislocation lines (one dimension), twin planes (two dimensions), and second phases (three dimensions). The flux lines remain pinned until the Lorentz force surpasses the pinning force of the defect.

Fig. 6 Critical current density, J_c , vs. the temperature and the external magnetic field.

Fig. 7 Current–voltage characteristic of a superconductor.

Superconducting Materials

Except for the elements vanadium, technetium, and niobium, the Type 2 category of superconductors includes compounds and alloys. Niobium ($T_c = 9.2\text{K}$), especially when alloyed with titanium ($\text{Nb}_{0.7}\text{Ti}_{0.3}$; $T_c = 9.8\text{K}$), exhibits the highest critical temperature of all elements. Although superconductors with higher T_c are available, until now, most commercially available superconducting magnets operating below about 5 T are based on NbTi wires, due to its comparably low price and excellent manufacturing qualities. During the late 1940s and early 1950s, compounds were found with T_c values in the range of 10–20K. These compounds belong to the β -tungsten structure family, also named A15 phases or A_3B structure (Flükiger, 1991). The unit cell of the structure consists of a cube with the B atoms entering each corner of the cube. The A atoms enter the planes of the cube, and so form lines parallel to each crystallographic direction of the crystal (Fig. 8). It is believed that this extraordinary structural feature is mainly responsible for the relatively high T_c s of the compounds. Due to technological considerations with respect to processing and fabrication, only Nb_3Sn ($T_c = 18.1\text{K}$) is used for the manufacturing of wires for high field ($> 5\text{ T}$) superconducting magnets.

Superconductivity has been found in different materials (Table 1), which indicates that superconductivity is not only related to one or two structural types, but may occur everywhere.

Magnesium Diboride

MgB_2 has been found to be superconducting at a T_c of 39 K and a B_{c2} at about 11 T (Nagamatsu *et al.*, 2001). This new Type 2 superconductor has a hexagonal structure (AB_2) with $a = 3.086\text{ Å}$ and $c = 3.524\text{ Å}$. Although the compound has quite low T_c and B_{c2} values (about 15 T at 4.2K and 10 T at 20K; up to 74 T in thin films at 4.2K), it is of considerable interest for the processing of

wires used for the construction of superconducting magnets operating at 1–2 T and 20K, due to its comparably low price and excellent workability. In addition, it is hoped that besides MgB₂ other superconducting compounds of this new class of superconductors with T_c s much higher than 39K will be found.

Iron Based Superconductors

In recent years a new class of superconducting materials were discovered that have a layered structure similar to high-temperature superconductors. These materials are based on iron phosphate or iron arsenate layers that alternate with layers consisting of the oxides of rare earth elements. These materials are named oxy-pnictides. This new class of superconducting materials have the potential for economically feasible magnetic levitation and lossless transmission of electric energy at the temperature well above that of liquid helium. First discovered in 2006 (Kamihara *et al.*, 2006) fluorine doped LaOFeP with alternating layers of Fe²⁺ P³⁻ and La³⁺ (O_{1-x}F_x)^{(2-x)-} has a T_c of only about 4K. It is obvious that fluorine doping is essential for introducing superconductivity in the material. By replacing phosphorous with arsenic the T_c jumps to 26K at a fluorine content of about 11 atom% (Kamihara *et al.*, 2008) (Fig. 9). This compound is tetragonal with $a = 0.403$ nm and $c = 0.874$ nm. The compound shows systematically decreasing lattice parameters with increasing fluorine doping at the O²⁻ site which is due to the smaller ionic radius of fluorine compared to oxygen. A major increase of T_c has been observed when lanthanum is replaced with praseodymium. The T_c of this compound increases to about 45K with an onset at 52K (Ren *et al.*, 2008). The synthesis of these materials is usually done at temperatures of 1250°C in argon atmosphere at ambient pressures using the precursor materials lanthanum arsenide or phosphide, iron arsenide or phosphide, lanthanum oxide, and lanthanum fluoride.

High-Temperature Superconducting Cuprates

Since the first high temperature superconductor (HTSC) based on copper oxide with the composition La_{0.85}Ba_{0.15}CuO₃ was found, a variety of high-temperature superconductors have been synthesized. They all share a single structural feature, namely superconducting two-dimensional sheets of CuO₂ consisting of corner-shared CuO₄ units (Park and Snyder, 1995). The sheets are separated by a nonsuperconducting layer which supplies the sheets with charge carriers. The HTSCs can be divided into three major groups: (1) REEBa₂Cu₃O_{7-x} (123 type); (2) AB₂Ca_{n-1}Cu_nO_{2n+2.5} (1223 type); (3) A₂B₂Ca_{n-1}Cu_nO_{2n+4} (2223 type) with REE = rare earth elements; A = Bi, Tl, Hg; B = Sr, Ba. The phases have a pronounced layered structure which is visible both microscopically (Fig. 10) and macroscopically (Fig. 11). Due to the significantly different parameters of the a , b , and c axis, the crystallization rate in direction of the a,b plane is about 10²–10³ times faster than in c direction.

Compared with low-temperature superconductors of Type 2, the cuprates behave very differently with respect to their superconducting properties vs. the temperature (Ginsberg, 1989; Lynn, 1990). Their resistivity transition is broader and the breadth increases rapidly with the applied field. This means that there is a region below B_{c2} where the material shows a substantial electrical resistance, although the material is superconducting with respect to quantum mechanical considerations. This region is shown in Fig. 12 between B_{c2} and the irreversibility line, B_{irr} . Below B_{irr} the resistance of the material is zero. The substantial resistance above B_{irr} corresponds to very easy flux flow.

The layered structure also implies a pronounced anisotropy of the properties, causing the so-called “two-dimensional superconductivity” parallel to the a,b plane. For example, the critical current density as well as the B_{c1} and B_{c2} values of the compounds, are significantly greater parallel to the a,b plane than parallel to the c axis (Fig. 13). In addition, due to the almost complete decoupling of the CuO₂ sheets by the nonsuperconducting (Bi, Tl, Hg)O sheets, the HTSCs behave very differently within an applied magnetic field. At temperatures below about 30K flux lines are formed above B_{c1} like in the Type 2 low-temperature superconductors. Above that temperature, the flux lines disappear and separated, almost two-dimensional, flux disks, the so-called

pancake vortices, are formed within the CuO_2 sheets (Fig. 14). The coupling between the pancakes is very weak, especially at high temperatures, for example 77K (boiling point of liquid nitrogen), so that the pancakes are moving independently from the neighboring pancake of the next CuO_2 sheet when a Lorentz force is applied. Pinning of these pancakes is almost impossible and therefore, the J_c decreases significantly in an applied magnetic field (Fig. 15).

Fig. 17 Micrograph of a 123 ceramic using an optical microscope and polarized light showing the [110] twin boundaries in 123 grains.

The Compound YBa₂Cu₃O_{7-x}

One of the main important high temperature superconducting cuprates is the compound YBa₂Cu₃O_{7-x}, better known as the “123 phase” ($T_c = 93\text{K}$) (Cava, 2001). The 123 phase is characterized by a Cu–O sublattice consisting of the CuO₂ sheets parallel to the crystallographic a–b plane, and Cu–O chains parallel to the crystallographic a axis (Fig. 16). The yttrium atom enters the center of the unit cell, and separates the Cu–O sheets. At temperatures of above 700°C the compound is tetragonal with $a = 3.857 \text{ \AA}$ and $c = 11.839 \text{ \AA}$. Below that temperature, the phase becomes orthorhombic with $a = 3.885 \text{ \AA}$, $b = 3.818 \text{ \AA}$, and $c = 11.680 \text{ \AA}$ due to the introduction of excess oxygen into the Cu–O chains.

The phase transformation is combined with a formation of elastic twins parallel to the crystallographic [110] plane. This phenomenon makes it easy to distinguish between the tetragonal and orthorhombic 123 phase using a microscope and polarized light (Fig. 17). Tetragonal YBa₂Cu₃O₆ is nonsuperconducting. With increasing oxygen content the compound becomes superconducting at about YBa₂Cu₃O_{6.3}. Maximum T_c is reached at YBa₂Cu₃O_{6.93}. A further increase of the oxygen content decreases T_c .

The 1223 and 2223 Type Compounds

The compounds have layered structures parallel to the crystallographic a,b plane, consisting of (Bi,Tl, Hg)O-layers which alternate with perovskite-like B₂Ca_{n-1}Cu_nO_{1+2n} units as illustrated in Fig. 18. The Sr₂Ca_{n-1}Cu_nO_{1+2n} units contain the CuO₂ sheets which are oriented parallel to the a,b plane. The $n = 2$ phase (1212 or 2212 phase) is characterized by two CuO₂ sheets and the $n = 3$

Fig. 18 (a) Crystal structure of the $A_2B_2Ca_2Cu_3O_{10}$ type HTSC with $A = \text{Bi, Tl, Hg}$, and $B = \text{Sr, Ba}$. (b) Crystal structure of the $AB_2Ca_2Cu_3O_{10}$ type HTSC with $A = \text{Tl, Hg}$, and $B = \text{Sr, Ba}$.

phase (1223 and 2223 phase) by three CuO_2 sheets, respectively. Thus, the general structure of all members of the series consist of CuO_2 sheets, that are separated by calcium (for $n > 1$) and covered in the c direction by $(\text{Ba, Sr})\text{O}$ sheets. These perovskite-like units alternate in c direction with the $(\text{Bi, Tl, Hg})\text{O}$ -layers.

The T_c s of the compounds are dependent on the oxygen content and, like the 123 phase, they exhibit a maximum T_c at a certain oxygen content. However, none of them become nonsuperconducting at low oxygen contents, and the dependence of T_c is very different from compound to compound (Majewski *et al.*, 1997a). The synthesis of the superconducting cuprates is rather straight forward and can be done in air or oxygen atmosphere using the generic oxides and carbonates (Majewski *et al.*, 1997b).

Iron Selenide Thin Films

Very recently, the discovery of superconductivity with T values up to 100K in FeSe thin films caused considerable excitement, as it opens the door to another avenue to high temperature superconductivity. Superconductivity with a T_c of up to 109K was observed in single-layer FeSe films deposited on SrTiO_3 (001) substrates (Ge *et al.*, 2015). Bulk FeSe samples were observed to have a T_c of only about 8K. However, substitution of Se with Te in the FeSe superconductor results in an increase of T_c up to 14.5K and superconductivity exists over a wide concentration range in the $\text{Fe}(\text{Se, Te})$ system, although pure FeTe is not superconducting (Liu *et al.*, 2015). Although the mechanism of high temperature superconductivity in FeSe single-layer thin films on SrTiO_3 has yet to be understood, the discovery of this novel phenomenon and the understanding of the fundamental physical mechanisms underlying this phenomenon can be the key to discovering superconductivity even at room temperature.

Superconductivity and Magnetism in Borocarbides

Superconductivity in quaternary rare-earth transition-metal borocarbides (RTBC) has been found in 1994 (Nagarajan *et al.*, 1994; Cava *et al.*, 1994). With the invention of these materials the new $\text{LuNi}_2\text{B}_2\text{C}$ -type structure (see Fig. 1), space group $14/mmm$, has been discovered which can be considered as the well-known ThCr_2Si_2 type interstitially modified by carbon. The $\text{RT}_2\text{B}_2\text{C}$ compounds are the $n = 1$ (so-called single layer) variants of $(\text{RC})_n\text{T}_2\text{B}_2$ structures where n RC layers alternate with single T_2B_2 layers. Details on the properties of these and related compounds can be found in the review articles listed in the Bibliography. Table 1 summarizes the known superconducting and non-superconducting RTBC compounds of $\text{LuNi}_2\text{B}_2\text{C}$ -type structure where R stands for 4f- and 5f-elements as well as for Sc, Y, and La. Among them $\text{YPd}_2\text{B}_2\text{C}$ has the highest superconducting transition temperature $T_c \approx 23$ K. However, no single-phase samples could be prepared of the particular compound so far. The growth of very high quality single-crystals of various RTBC almost immediately after their discovery has had a profound impact on the quality of the work performed.

For certain combinations of elements R and T , superconducting and antiferromagnetic order have been found to coexist. The magnetic moments in these materials are localized at the R -sites whereas the Ni d-electrons are nearly non-polarized. A striking feature distinguishing the superconducting RTBC from other superconductors known until 1994 is that the magnetic ordering temperature T_N is comparable with T_c (see Fig. 2), i.e., the magnetic energy is comparable with the superconducting condensation energy. Therefore, the investigation of these compounds is expected to result in new insights into the interplay of superconductivity and magnetism. The high values of T_N demand that in RTBC, different from the situation in high- T_c cuprates and the classical magnetic superconductors, exchange coupling between the rare-earth magnetic moments is the dominant magnetic interaction rather than magnetostatic interaction. Obviously the exchange is mediated by conduction electrons. Consequently, also the interaction between the magnetic moments and the conduction electrons must be relatively strong. Fig. 2 shows a linear scaling of T_N and, roughly approximated, also of T_c with the de Gennes factor $\text{DG} = (g - 1)^2(J + 1)$ of the R^{3+} Hund's rule ground state where g is the Landé factor and J is the total angular momentum. Such so-called de Gennes scaling, at the same time for T_N and T_c is due the fact that both effects, antiferromagnetism and the suppression of superconductivity, are governed by the exchange interaction of the conduction electrons with the R 4f-electrons. According to Fig. 2, $\text{YbNi}_2\text{B}_2\text{C}$ should be a superconductor becoming antiferromagnetically ordered at sufficiently low temperatures. In this compound, however, hybridization of 4f-electrons with the conduction electrons connected with correlation effects result in heavy fermion behavior and suppression of superconductivity.

Fig. 2 Critical temperatures for superconductivity, T_c , and for antiferromagnetic ordering, T_N , of $\text{RNi}_2\text{B}_2\text{C}$ compounds with $R = \text{Lu, Tm, Er, Ho, Dy, Tb, and Gd}$. DG , g , and J are explained in the text. The straight lines represent linear approximations.

The RTBC superconductors have been classified as phonon-mediated type II superconductors in the clean limit (i.e., the mean free path of the unpaired electrons is large compared to the coherence length of the Cooper pairs). The symmetry of the superconducting gap will be discussed in the next section.

Symmetry of the Superconducting Gap

The symmetry of the superconducting order parameter is a fundamental property used to distinguish conventional from unconventional superconductors. In the latter case, the symmetry of the superconducting order parameter is lower than that of the crystal structure (the same as that of the Fermi surface). The quasiparticles in the superconducting state acquire a gap near the Fermi level reflecting the symmetry of a Cooper pair, which can be identified with the superconducting order parameter. The wave function of Cooper pairs in non-magnetic $\text{RNi}_2\text{B}_2\text{C}$ compounds is given by the product of an orbital and a spin part. In the case of singlet pairing with total spin $S = 0$, the orbital part must be of even parity and can be classified by an even total angular momentum $l = 0, 2, 4$, denoted as s -, d -, and g -wave states, respectively. Then, a pure s -wave state has no zeros (nodes) and a constant gap Δ , whereas in the more realistic extended s -wave state the gap $\Delta(k)$ changes over the Fermi surface, i.e., it becomes anisotropic. In contrast, a pure d - or g -wave state may exhibit point-like nodes.

The nature of the quasiparticle energy gap is one of the most challenging questions in the research on $\text{RNi}_2\text{B}_2\text{C}$. A few years after their discovery these compounds were assumed to be conventional s -wave superconductors with an anisotropic gap (Müller *et al.*, 2002). Later, an analysis of the upper critical field (Wang and Maki, 1998) and the field dependence of the specific heat suggested d -wave superconductivity (Nohara *et al.*, 1997). However, the strong influence of Pt substitutions for Ni on the gap (Yokoya *et al.*, 2000) quite certainly rules out such a line-node scenario.

A phenomenological model with an $(s+g)$ -wave symmetry of the gap function was proposed by Lee and Choi (2002) in order to interpret experimental data for the angle-dependent thermal conductivity (see Fig. 3(a)) and specific heat in the frame of a single band model. In particular, Maki *et al.* (2002) used the form $\Delta(k) = 1/2\Delta(1 - \sin^4\theta \cos(4\phi))$, where θ and ϕ are the polar and the azimuthal angle in the k space, respectively. This model leads to four point nodes in the energy gap located regularly in the a - b -plane and describes the angular variation of both the c -axis component of the thermal conductivity and the specific heat C in

Fig. 3 Angular-dependent c-axis thermal conductivity of $\text{YNi}_2\text{B}_2\text{C}$ (a-left panel). θ and ϕ are defined in the inset. The right panel (b) shows the gap symmetry in the case of point nodes ($(s + g)$ -wave) and, additionally, the resulting angular variation of a quantity I_{zz} that is proportional to the c-axis component of the thermal conductivity. From Isawa, K., Kamata, K., Nakayima, Y., *et al.*, 2002. Gap function with point nodes in borocarbide superconductor $\text{YNi}_2\text{B}_2\text{C}$. Phys. Rev. Lett. 89, 137006.

$\text{YNi}_2\text{B}_2\text{C}$ in an in-plane magnetic field. In particular, the observed four-fold oscillations of the c-axis component of κ and C with narrow cusps (especially for $\theta = 90^\circ$) are reproduced by this model as shown in Fig. 3(b) for the thermal conductivity of $\text{YNi}_2\text{B}_2\text{C}$. A generalization for any direction of the applied field was given by Thalmeier and Maki (2003). The angle-dependent thermal conductivity was found to be strongly influenced by the presence of impurities (Yuan *et al.*, 2003; Maki *et al.*, 2004). A theoretical study by Yuan and Thalmeier (2003) has confirmed the stability of the mixed gap function. The $(s + g)$ -wave model has been described in detail by Thalmeier and Zwicknagl (2005).

An alternative explanation of the cusp-like singularity in the angle-dependent thermal conductivity and the specific heat was given by Udagawa *et al.* (2005). They calculated the field-orientational dependence of the density of states (FODOS) based on the solution of the Eilenberger equation and found rather broad minima in the point-node case. The FODOS is strongly influenced by the local Fermi surface part and its order parameter, but not so strong by the entire global nodal structure. In $\text{YNi}_2\text{B}_2\text{C}$, the Fermi surface nesting leads to a quasi two-dimensional nature of one of the conduction-electron bands. Assuming a two-band model with an isotropic superconducting coherence length, cusp-like minima are attributed to nesting effects rather than to a contribution from a nodal gap structure. A theoretical study based on the quasi-classical Eilenberger formalism (Miranović *et al.*, 2005) supported the interpretation of the rotational-field experiments. It was pointed out, however, that more detailed low-field data are required to distinguish between gap nodes and non-zero gap minima. A detailed analysis of the specific heat of $\text{YNi}_2\text{B}_2\text{C}$ has been presented by Huang *et al.* (2006). The zero-field data were compared with the predictions of different theoretical models (Fig. 4). Good agreement was found for a point-node scenario with $\Delta = \Delta_0 \sin n\theta$, where θ is the polar angle in the k space. Alternatively, an excellent description of the data is attained employing a two-band model, whereas an isotropic s-wave or line-node scenario can be ruled out. It is noted that the $(s + g)$ -wave model results in $C_p \sim T^2$ (Yuan *et al.*, 2003), which is significantly different from the usually observed T^3 dependence.

Thus, measurements of the thermal conductivity κ and the specific heat C provided first hints supporting the extended s-wave scenario in which electrons from different bands are involved in the pairing mechanism. Whereas discrepancies become visible in case of a single-band description of the experimental data within the $(s + g)$ -wave model. A large number of studies on the gap symmetry of $\text{RNi}_2\text{B}_2\text{C}$ including NMR results was summarized by Brandow (2003) who suggested strongly anisotropic s-wave superconductivity and pointed out that a single-band description might oversimplify the interpretation of experimental data due to the complex Fermi surface in $\text{RNi}_2\text{B}_2\text{C}$.

These results have been confirmed by point-contact spectroscopy (Bashlakov *et al.*, 2005, 2007), scanning tunneling spectroscopy (Martínez-Samper *et al.*, 2003; Suderow *et al.*, 2003) and photoemission spectroscopy data (Yokoya *et al.*, 2000; Baba *et al.*, 2006), too. These techniques provide a local insight, especially into the structure of the superconducting gap.

Fermi Surface in Non-magnetic Borocarbides in the Normal and Superconducting State

The knowledge of the electronic structure near the Fermi energy is a key for the understanding of mechanism of superconductivity. Band structure calculations for $\text{YNi}_2\text{B}_2\text{C}$ and $\text{LuNi}_2\text{B}_2\text{C}$ revealed a 3D band structure with rather complicated band components near the Fermi level. Experimentally, the de Haas van Alphen (dHvA) effect associated with the quantization of electron orbits in a magnetic field is a powerful tool for directly probing the Fermi surface of metals in the normal state. From dHvA oscillations on high-quality $\text{LuNi}_2\text{B}_2\text{C}$ single crystals in magnetic fields up to 32 T, several dHvA frequencies have been resolved in the normal state well above the upper critical field corresponding to five extremal Fermi-surface orbits, which are shown in Fig. 5. (Bergk *et al.*, 2008).

Fig. 4 Temperature-dependent electronic contribution C_e to C_p (circles) and fits (thick lines) to various models: (a) line node gap; (b) point node gap with $\Delta = \Delta_0 \sin n\theta$; (c) $(s+g)$ wave; (d) two-gap, where the thin lines show the C_e/T for the larger and the smaller gap. The respective insets show the absolute difference DF between calculation and measured data. From Huang, C.L., Lin, J.Y., Sun, C.P., *et al.*, 2006. Comparative analysis of specific heat of $\text{YNi}_2\text{B}_2\text{C}$ using nodal and two-gap models. *Phys. Rev. B* 73, 012502.

The observation of quantum oscillations in the superconducting state has been controversially discussed even more due to contradictory experimental data. The opening of a superconducting gap below H_{c2} seems to exclude the existence of quantum oscillations at first glance, because the entire Fermi surface might be disturbed by the flux line lattice. But nevertheless, dHvA oscillations have been observed in the mixed state of many type II superconductors (Harrison *et al.*, 1994 and citations within), and, in particular, in non-magnetic borocarbide superconductors (Bergk *et al.* 2008, 2012), too. Several models have been proposed to explain this behavior, but a profound theory describing quantum oscillations of elaborated Fermi surfaces down to lower fields deep inside the superconducting state is still missing.

The dHvA oscillation in the borocarbides in the mixed state are dominated by the so-called α pocket (see Fig. 5, upper panel), although the electrons of this Fermi surface sheet contribute only about 1% to the density of states. Thus, this Fermi surface plays a very minor role for the superconductivity in these compounds, which is a strong argument for a multi-band scenario.

Controversially experimental data have been reported for the α pocket in the mixed state. Both an additional damping of the dHvA signal (Goll *et al.*, 1996) and an unexpectedly small gap (Bergk *et al.*, 2012) or even an abruptly vanishing of the oscillations below B_{c2} (Ignatchik *et al.*, 2005) have been reported for the α pocket in $\text{YNi}_2\text{B}_2\text{C}$ and $\text{LuNi}_2\text{B}_2\text{C}$. Remarkably, significantly different data have been obtained with different experimental techniques, as the magnetic torque, a field-modulation or an ultrasound method, presumably because of the induced order in the flux-line lattice, when modulating the magnetic field or by applying ultrasound waves.

In order to clarify this question, quantum-oscillation data for the same $\text{YNi}_2\text{B}_2\text{C}$ single crystal were measured by the ultrasound and by the magnetic-torque method (Noessler *et al.*, 2017). By using the ultrasound method, magneto-acoustic quantum oscillations deep inside the mixed state of $\text{YNi}_2\text{B}_2\text{C}$ could be resolved. The frequency of this oscillation has been ascribed to the α pocket. Only a very weak additional damping of the dHvA data was observed below B_{c2} that was found to be consistent with the weak field inhomogeneity related to an ideal hexagonal flux-line lattice. This small damping of the dHvA signal in the mixed state was interpreted as evidence for no or a vanishingly small gap for the α pocket. In contrast, a rapidly vanishing dHvA signal was obtained below B_{c2} by the magnetic-torque method. The direct comparison between torque and ultrasound data on the same sample provides evidence that the strong damping of the torque dHvA signal below B_{c2} cannot be related to the opening of the superconducting gap of the α pocket. Instead, this effect is likely caused by a strongly distorted flux-line lattice. Whereas the persistence of the magneto-acoustic quantum oscillations down to very low fields in the mixed state points to a rearrangement of the vortices into a regular flux-line lattice under the influence of sound waves. It was argued that sound waves do not directly shake vortices as it is known from oscillating magnetic fields, but they might shake pinning centers which in return could rearrange the vortices (Noessler *et al.*, 2017).

Fig. 5 Fermi surfaces (FS) in $\text{LuNi}_2\text{B}_2\text{C}$ identified from dHvA oscillations: spherical FS (upper panel), cubic and cushion-like FSs (middle panel) and branched FS (lower panel) corresponding to the dHvA frequencies F_z , F_{α} , F_{η} and F_{σ} , respectively. From Bergk, B., Petzold, V., Rosner, H., *et al.*, 2008. Anisotropic multiband many-body interactions in $\text{LuNi}_2\text{B}_2\text{C}$. *Phys. Rev. Lett.* 100, 257004.

The surprising result of an extremely small gap for the α pocket can be explained within a realistic multiband approach by a field-induced quenching of superconductivity in the α pocket well below B_{c2} . Such partial quenching of superconductivity by an external magnetic field in a multi-band superconductor was predicted for a weakly with otherwise strongly coupled bands at low temperatures (Barzykin and Gor'kov, 2007). Indeed, rather modest upper critical fields $B_{c2}^2(0)$ between 0.39 and 0.45 T were estimated for the α pocket (Noessler *et al.*, 2017) implying that superconductivity in the α pocket should be quenched at fields well below 3 T above which the dHvA oscillations could be resolved.

Upper Critical Field for Non-Magnetic Borocarbides

The upper critical field $B_{c2}(T)$ as a fundamental quantity of type-II superconductors provides insight into the coupling strength, the electronic structure, the symmetry and anisotropy of the order parameter and the presence of various disorder-related scattering processes. All these factors affect the magnitude, the shape and the anisotropy of $B_{c2}(T)$.

The reported experimental data on the upper critical field B_{c2} of $\text{YNi}_2\text{B}_2\text{C}$ and $\text{LuNi}_2\text{B}_2\text{C}$ scatter considerably due to paramagnetic signals from impurities which are difficult to avoid in the nominally non-magnetic borocarbides (Mun *et al.*, 1998). Nevertheless it has clearly been shown for both compounds that B_{c2} is anisotropic not only with respect to the tetragonal c axis and the basal plane but also within that plane (Metlushko *et al.*, 1997; Wimbush *et al.*, 2004).

The out-of-plane anisotropy can be described within the phenomenological one-band Ginzburg-Landau theory of superconductivity (Ginzburg and Landau, 1950) or its microscopic derivation from the BCS theory (Gor'kov, 1959) by an effective mass anisotropy. In the case of $\text{LuNi}_2\text{B}_2\text{C}$ the degree of the out-of-plane anisotropy of B_{c2} is nearly temperature independent and the resulting mass anisotropy, $m_c^*/m_a^* \approx 1.35$, is in good agreement with the Fermi surface anisotropy determined from band-structure calculations (Mattheiss, 1994).

Fig. 6 $H_{c2}(T)$ of an $\text{LuNi}_2\text{B}_2\text{C}$ single crystal measured parallel to the tetragonal c -axis (●). The solid curve was calculated using a two-band model. Dashed lines: isotropic single-band model for two different scattering rates. After Shulga, S.V., Drechsler, S.L., Fuchs, G., *et al.*, 1998. Upper critical field peculiarities of superconducting $\text{YNi}_2\text{B}_2\text{C}$ and $\text{LuNi}_2\text{B}_2\text{C}$. *Phys. Rev. Lett.* 80, 1730.

The in-plane anisotropy of H_{c2} cannot be explained within the (local) GL theory, but by its non-local extension introduced by Hohenberg and Werthamer (1967). The anisotropy of the Fermi surface sheets has been assumed to cause the mentioned basal anisotropy of B_{c2} . Taking non-local corrections to H_{c2} due to the anisotropic Fermi surface into account, experimental $B_{c2}(T, \phi)$ data for $\text{LuNi}_2\text{B}_2\text{C}$ (with ϕ as the angle in the basal plane) have been described by an analytical expression (Metlushko *et al.*, 1997). In this expression, averages of the Fermi velocity are used, which can be estimated from electronic-structure calculations or taken as fitting parameters.

A special feature of the temperature dependence of B_{c2} found for the non-magnetic borocarbides $\text{YNi}_2\text{B}_2\text{C}$ and $\text{LuNi}_2\text{B}_2\text{C}$ is its positive curvature near T_c , which does not occur in the standard BCS theory. Such an upward curvature has been observed in all crystal orientations, for both, $\text{LuNi}_2\text{B}_2\text{C}$ and $\text{YNi}_2\text{B}_2\text{C}$. An example is shown in Fig. 6. It is clearly seen that the single band model cannot explain neither the large $B_{c2}(0)$ (using a reasonable impurity scattering rate of $\gamma_{\text{imp}} = 17 \text{ cm}^{-1}$) nor the positive curvature of $B_{c2}(T)$ near T_c . The anomalous S-like shape of $B_{c2}(T)$, as compared with the standard parabolic-like Werthamer-Helfand-Hohenberg (WHH) behavior, has been analyzed by Shulga *et al.* (1998) within the microscopic Eliashberg theory of superconductivity. In order to reproduce the experimental $B_{c2}(T)$ data, they considered two bands with different Fermi velocities, where one of the two Fermi velocities, v_{F1} , is considerably smaller than the Fermi-surface average of v_F . These slow electrons have a strong electron-phonon coupling and are mainly responsible for the superconductivity. It is noteworthy that the slow electrons in $\text{LuNi}_2\text{B}_2\text{C}$ and $\text{YNi}_2\text{B}_2\text{C}$ stem from nested regions on the Fermi surface, whereas in the non-superconducting compound $\text{LaNi}_2\text{B}_2\text{C}$ there is no nesting and, consequently, a smaller dispersion of v_F (Rosner *et al.*, 2001).

The two-band description of B_{c2} has been confirmed by subsequent theoretical studies (Drechsler *et al.*, 2001; Nicol and Carbotte, 2005) that are also extended on further thermodynamic properties. A similar approach using an anisotropic electron-phonon interaction spectral function (Manalo and Schachinger, 2001) also leads to good agreement with the experimental data.

In the example of Fig. 6, the experimental $B_{c2}(T)$ curve can be well reproduced by taking the velocity ratio $v_{F2}/v_{F1} \approx 4.5$ and adjusting the other input parameters of the two-band model to experimental data from the literature. Within the two-band model, both, the value $H_{c2}(0)$ and the degree of positive curvature, can be considerably varied by changing the scattering rate γ_{imp} (Shulga and Drechsler, 2001; Gurevich, 2003). As expected, in the clean limit, B_{c2} decreases with increasing interband scattering γ_{imp} . This prediction has been experimentally confirmed for pseudoquaternary $(\text{Lu}, \text{Y})\text{Ni}_2\text{B}_2\text{C}$ compounds where an increase of substitutional disorder results in a decrease of $B_{c2}(T)$ (Fuchs *et al.*, 2001).

Interplay Between Superconductivity and Magnetism in $\text{HoNi}_2\text{B}_2\text{C}$

$\text{HoNi}_2\text{B}_2\text{C}$ is one of the most interesting compounds among the borocarbide superconductors. As can be seen in Fig. 7(a), resistivity-vs.-temperature curves show a sharp transition into the superconducting state at $T_c \approx 8 \text{ K}$ in zero-magnetic field. Near-reentrant superconductivity is observed at small fields. Fig. 7(a) also shows that the temperature range near T_N where the reentrant behavior occurs does not much depend on the magnetic field indicating a magnetic phase transition at T_N . This is supported also by measurements of the specific heat C_p (see Fig. 7(b)) that shows a peak near T_N . Interestingly, two further features can be seen in Fig. 7(b) at T^* and T_M , indicating two other magnetic-ordering phenomena. On the other hand, no anomaly of C_p at T_c can be seen in Fig. 7(b). This has been attributed to the fact that the high-temperature tails of the C_p anomalies at T_N , T^* , and T_M are still higher at T_c than the expected jump in C_p associated with the superconducting transition (Canfield *et al.*, 1994).

Antiferromagnetic Order in $\text{HoNi}_2\text{B}_2\text{C}$

Three different types of antiferromagnetic order occur in $\text{HoNi}_2\text{B}_2\text{C}$ at zero magnetic field (Grigereit *et al.*, 1994; Goldman *et al.*, 1994) as was shown by elastic neutron diffraction. Upon cooling, the commensurate antiferromagnetic structure of Fig. 8(a) forms

Fig. 7 (a) Resistivity vs. temperature measured at different magnetic fields H on a polycrystalline $\text{HoNi}_2\text{B}_2\text{C}$ sample. T_c is the superconducting transition temperature at $H = 0$. A near-reentrant behavior occurs around a temperature T_N . (b) Temperature dependence of the specific heat C_p of a $\text{HoNi}_2\text{B}_2\text{C}$ single crystal measured at zero magnetic field. Above the main peak of $C_p(T)$ at T_N , two additional features appear at T^* and T_M . No jump in C_p can be seen at T_c . From Müller, K.H., Schneider, M., Fuchs, G., Drechsler, S.L., 2008. Fig. 8 Magnetic structures of $\text{HoNi}_2\text{B}_2\text{C}$ as determined by neutron scattering. (a) Commensurate antiferromagnetic. (b) Incommensurate c^* structure (spiral) with the modulation vector $\tau_2 = (0,0,0.916)$. (c) Proposed incommensurate a^* structure (after Kreyssig, A., Schneidewind, A., Loewenhaupt, M., et al., 2001. Magnetoelastic effects in rare earth nickel borocarbides. In: Müller, K.H., Narozhnyi, V.N. (Eds.), Rare Earth Transition Metal Borocarbides (Nitrides): Superconducting, Magnetic and Normal State Properties. Kluwer Academic Publishers, p. 181) with the modulation vector $\tau_3 = (0.585,0,0)$. From Müller, K.H., Schneider, M., Fuchs, G., Drechsler, S.L., 2008. Rare-earth nickel borocarbides. In: Gscheidner Jr., K.A., Bünzli, J.-C.G., Pecharsky, V.K. (Eds.), Handbook of the Physics and Chemistry of rare earths, vol. 38. Amsterdam: Elsevier, p. 175.

at $T_N \approx 5.2\text{K}$ consisting of ferromagnetic sheets in the tetragonal basal plane. Additionally, in the temperature range $T_N < T < T_c$ there is an incommensurate spiral structure along the tetragonal c axis, where the magnetic moments are ferromagnetically aligned in the a - b -plane as in the ground state. The ferromagnetic sheets in adjacent layers have a relative orientation of about 163.4° instead of 180° for the ground state (see Fig. 8(b) and (a)). Furthermore, in a small temperature range above T_N an a -axis modulated incommensurate magnetization structure occurs with a modulation vector $\tau_3 \approx (0.58,0,0)$ which is close to the nesting vector $q \approx (0.55,0,0)$ known from other borocarbide superconductors, in particular $\text{LuNi}_2\text{B}_2\text{C}$ and $\text{YNi}_2\text{B}_2\text{C}$ (see Section "Fermi Surface in Non-Magnetic Borocarbides in the Normal and Superconducting State"). The exact form of this a^* structure is still unknown. From results of neutron diffraction experiments on powder samples Kreyssig *et al.* (2001) concluded that the a^* structure has an oscillating component of magnetic moments in the a - b -plane as outlined in Fig. 8(c). Also a study by Detlefs *et al.* (2000) of metamagnetic phases suggests that the a^* structure has only magnetic moments perpendicular to the c axis.

For magnetic fields H applied perpendicular to the tetragonal c axis of $\text{HoNi}_2\text{B}_2\text{C}$ single crystals, measurements of magnetization and elastic neutron diffraction show up to three metamagnetic transitions (see Fig. 9; Canfield *et al.*, 1997). It was concluded that in a strength-of-field vs. angle-of-field phase diagram, besides the paramagnetic phase at elevated temperatures and the simple antiferromagnetic phase ($\uparrow\downarrow$) at low temperatures and low fields, two additional metamagnetic phases occur for sufficiently high fields which are denoted in Fig. 10 (left panel) by the arrow combinations $\uparrow\uparrow\downarrow$ and $\uparrow\uparrow\rightarrow$. Here it is assumed that in all of the magnetically ordered phases the local magnetic moments are directed along those $[110]$ axes that are either near parallel (arrow $\uparrow$) or near antiparallel ($\downarrow$) or near perpendicular ($\rightarrow$) to the applied field.

Fig. 9 Magnetization vs. applied field at $T = 2\text{K}$ for $H \perp c$ with the angle $\theta = 20^\circ$ between applied field and $[110]$ axis. Three metamagnetic transitions are observed: (1) from the simple antiferromagnetic structure $\uparrow\downarrow$ to a first metamagnetic phase $\uparrow\uparrow\downarrow$, (2) to a second metamagnetic phase $\uparrow\uparrow\rightarrow$ and (3) to the paramagnetic structure $\uparrow\uparrow$. From Canfield, P.C., Bud'ko, S.L., Cho, B.K., *et al.*, 1997. Angular dependence of metamagnetic transitions in $\text{HoNi}_2\text{B}_2\text{C}$. Phys. Rev. B 55, 970.

Fig. 10 Magnetic phase diagrams of $\text{HoNi}_2\text{B}_2\text{C}$. (a - left panel) H - θ phase diagram at $T = 2\text{K}$, where H is perpendicular to the c axis and has an angle θ with respect to the nearest magnetically easy $[110]$ direction. $\uparrow\downarrow$ is the antiferromagnetic phase shown in Fig. 8 (a); the metamagnetic phases $\uparrow\uparrow\downarrow$, $\uparrow\uparrow\rightarrow$ and $\uparrow\uparrow$ are described in the text (after Canfield, P.C., Bud'ko, S.L., Cho, B.K., *et al.*, 1997. Angular dependence of metamagnetic transitions in $\text{HoNi}_2\text{B}_2\text{C}$. Phys. Rev. B 55, 970). (b - right panel) Field H applied along the tetragonal a axis (i.e., $\theta = \pm 45^\circ$). Here para means the paramagnetic phase steadily changing, with increasing H , into the saturated (ferromagnetic) state $\uparrow\uparrow$ which, at low temperatures, is a metamagnetic phase. After Detlefs, C., Bourdarot, F., Burlet, P., *et al.*, 2000. Ordering wave vectors of metamagnetic states in $\text{HoNi}_2\text{B}_2\text{C}$: One dimension is not enough. Phys. Rev. B 61, R14916.

Detlefs *et al.* (2000 and, 2001) found by elastic neutron diffraction at 2K that the second metamagnetic phase ($\uparrow\uparrow\rightarrow$) has a modulation vector $\tau_3 \approx (4/7, 0, 0)$ which is close to the nesting vector $q \approx (0.55, 0, 0)$. The presence of an a^* -metamagnetic phase at 2K is supported by results of Kreyssig *et al.* (1999) who performed elastic neutron-diffraction experiments on $\text{HoNi}_2\text{B}_2\text{C}$ powders and also detected different metamagnetic phases.

The extension of the boundaries between the metamagnetic phases to the zero-field boundaries at T_N , T^* and T_M , as shown in Fig. 10 (right panel), has also been supported by specific-heat measurements by Choi *et al.* (2001) and Park *et al.* (2004). The transition at T_N is of first order. The magnetic phase transition at T^* is described as a change from an a^* -dominant phase to a c^* -dominant phase, and it cannot be excluded that it is also of first order (Park *et al.*, 2004). A first-order transition at T^* would explain the fact that both phases, a^* and c^* coexist above as well as below T^* , as has been confirmed by elastic neutron diffraction experiments on a $\text{HoNi}_2\text{B}_2\text{C}$ single crystal.

Two microscopic approaches have been presented in literature, which, until recently, had been believed to reasonably describe the magnetic phase diagram of Fig. 10(b).

Amici and Thalmeier (1998) used a quasi-one-dimensional model assuming ferromagnetically ordered Ho layers with the magnetic moments oriented perpendicular to the tetragonal c axis. The competition of the RKKY interaction along the c axis with

the crystalline electric field is analyzed in order to determine the transition between the commensurate antiferromagnetic structure and the incommensurate c^* spiral shown in Fig. 8.

The so-called clock model of Kalatsky and Pokrovsky (1998) is also a semiclassical approximation which starts with the assumption that the strong single-ion anisotropy confines the Ho magnetic moments to the four [110] directions. Both models predict the phase boundaries of Fig. 10(b) and the temperature dependence of the c -axis commensurate-to-incommensurate transition surprisingly well. However both models cannot explain the nature and origin of the a^* phase observed at zero field or at a finite field as reported by Detlefs *et al.* (2000). Possibly these problems can only be solved by a more detailed description of the RKKY interaction, taking into account the Fermi-surface-nesting features.

The field-induced first-order metamagnetic transition from the antiferromagnetic to a ferromagnetic state observed at low temperature (see Fig. 10(a)) was found to be accompanied by a giant magnetocaloric effect (MCE) (El Massalami *et al.*, 2004). For a magnetic field change of 5 T, a maximum adiabatic temperature change of $\Delta T_{\max} \sim 11$ K has been found for $\text{HoNi}_2\text{B}_2\text{C}$. A MCE has been reported for other antiferromagnetic borocarbide superconductors as $\text{DyNi}_2\text{B}_2\text{C}$ and $\text{ErNi}_2\text{B}_2\text{C}$, too (Li *et al.*, 2011). The corresponding values of the maximum adiabatic temperature change at a field change of 5 T are $\Delta T_{\max} \sim 9.7$ and 4.6 K for $R = \text{Dy}$ and Er , respectively. Remarkably, an inverse MCE, i.e., a negative temperature change ΔT due to a change of the applied magnetic field, was observed under low magnetic field ($\Delta B = 2$ T) and at low temperature for $R = \text{Ho}$, Dy and Er (Li *et al.*, 2011). Generally, this occurs in antiferromagnetic materials, in which the applied magnetic field enhances the magnetic entropy.

Reentrant and Near-Reentrant Behavior

It is generally accepted that single-phase stoichiometric $\text{HoNi}_2\text{B}_2\text{C}$ exhibits the near-reentrant behavior presented in Fig. 7(a). It is obvious that the commensurate antiferromagnetic structure of Fig. 8(a) coexists with superconductivity in $\text{HoNi}_2\text{B}_2\text{C}$. On the other hand, as can be seen in Fig. 11(a) and (c) the superconductivity is suppressed over the small temperature range where the two incommensurate magnetic structures of Fig. 8(b) and (c) occur. However, in $\text{Y}_{0.15}\text{Ho}_{0.85}\text{Ni}_2\text{B}_2\text{C}$ the situation is quite different, as shown in Fig. 11(b) and (d). Here the a^* structure again is localized at the same temperatures as the reentrant behavior but the c^* spiral exists over a broad range of temperature. Thus, the a^* structure is more closely related to the near-reentrant superconductivity in $\text{Y}_{0.15}\text{Ho}_{0.85}\text{Ni}_2\text{B}_2\text{C}$ (as well as in $\text{Lu}_{0.15}\text{Ho}_{0.85}\text{Ni}_2\text{B}_2\text{C}$, Freudenberg *et al.* (1998)) than the c^* spiral.

NiIt was theoretically shown by Machida *et al.* (1980) that if antiferromagnetic ordering is connected with Fermi surface nesting the superconducting state may be heavily disturbed. For $\text{HoNi}_2\text{B}_2\text{C}$ the strong correlation between the near-reentrant behavior and the a^* magnetic ordering has first been emphasized by Müller *et al.* (1997) and has been confirmed also by Canfield and Bud'ko (2001). The conclusion that the a^* structure is more relevant for the near-reentrant behavior in $\text{HoNi}_2\text{B}_2\text{C}$ has been further confirmed by data for $\text{Y}_{0.15}\text{Ho}_{0.85}\text{Ni}_2\text{B}_2\text{C}$.

However, Dertinger *et al.* (2001) found that the a -axis modulated structure a^* of Fig. 8 is much more sensitive to pressure, compared to the other two magnetic structures of Fig. 7, and it even disappears at relatively low values of pressure. Interestingly he observed near-reentrant behavior also at temperatures and pressures where the a^* structure had disappeared. Therefore he

Fig. 11 (a) and (b): Resistivity vs. temperature curves for polycrystalline $\text{HoNi}_2\text{B}_2\text{C}$ and $\text{Y}_{0.15}\text{Ho}_{0.85}\text{Ni}_2\text{B}_2\text{C}$ samples, respectively, showing reentrant behavior in small magnetic fields. (c) and (d): The comparison with the neutron diffraction peak intensities shows that the a^* structure is strongly related to the reentrant behavior. T_N and T_M have been determined from the minima and the maxima, respectively, in (a) and (b); these values largely agree with T_N and T_M determined from specific heat data. From Müller, K.H., Schneider, M., Fuchs, G., Drechsler, S.L., 2008. Rare-earth nickel borocarbides. In: Gscheidner Jr., K.A., Bünzli, J.-C.G., Pecharsky, V.K. (Eds.), Handbook of the Physics and Chemistry of rare earths, vol. 38. Amsterdam: Elsevier, p. 175.

Fig. 12 High-quality $\text{HoNi}_2\text{B}_2\text{C}$ single crystal at zero magnetic field. Upper panel: specific heat with special features at temperatures T_N , T^* and T_M (as in Fig. 7(b)); Lower panel: energy gap determined by point-contact spectroscopy and fitted to the BCS gap formula. After Müller, K.H., Fuchs, G., Drechsler, S.L., *et al.*, 2007. Multiband superconductivity in $\text{HoNi}_2\text{B}_2\text{C}$. *Physica C* 460-462, 99.

Fig. 13 Temperature dependence of the upper critical field H_{c2} of a well-annealed $\text{HoNi}_2\text{B}_2\text{C}$ single crystal measured in the [110] and [001] directions. $H_{c2}(T)$ shows a significant anisotropy above T_N and a near-reentrant behavior, i.e., $H_{c2}(T)$ has a pronounced minimum near T_N but it never disappears. The arrow combinations $\uparrow\uparrow\downarrow$, $\downarrow\downarrow\uparrow$, $\uparrow\uparrow$ correspond to a metamagnetic, the antiferromagnetic and the paramagnetic phase, respectively. After Müller, K.H., Fuchs, G., Drechsler, S.L., *et al.*, 2007. Multiband superconductivity in $\text{HoNi}_2\text{B}_2\text{C}$. *Physica C* 460-462, 99.

concluded that the near-reentrant behavior in $\text{HoNi}_2\text{B}_2\text{C}$ cannot mainly be caused by the presence of the a^* incommensurate magnetic structure. Thus further experiments have to be done to elucidate the connection between (near-) reentrant behavior and the various magnetic structures in $\text{HoNi}_2\text{B}_2\text{C}$.

Multiband Coexistence of Superconductivity and Magnetism in $\text{HoNi}_2\text{B}_2\text{C}$

As has been shown in Section “Fermi Surface in Non-Magnetic Borocarbides in the Normal and Superconducting State”, the superconducting properties of the non-magnetic borocarbides $\text{YNi}_2\text{B}_2\text{C}$ and $\text{LuNi}_2\text{B}_2\text{C}$, and in particular the behavior of the upper critical field H_{c2} , can only be understood by taking into account at least two electron bands of the Fermi surface. Thus, an

interesting question is whether such multiband concept is needed also in the case of the local-moment antiferromagnetic superconductor $\text{HoNi}_2\text{B}_2\text{C}$ and how it explains the interplay of magnetism and superconductivity in this compound (Müller *et al.*, 2007). As can be seen in Fig. 6, the transition temperature of a well prepared $\text{HoNi}_2\text{B}_2\text{C}$ single crystal has been found to be as high as $T_c = 8.8\text{K}$. However, the energy gap determined by point-contact spectroscopy can be well fitted to a BCS gap function vanishing at $T = T^* \approx 5.6\text{K}$ as shown in Fig. 12 (Naidyuk *et al.*, 2007) where the specific heat has a special feature that has been attributed to a change, with increasing temperature, from a c^* dominated to an a^* dominant magnetic phase (Park *et al.* 2004). Although the magnitude and the temperature dependence of the (small) superconducting gap in the range $T^* \leq T \leq T_c$ is not yet well investigated, gapless superconductivity (as proposed by Rybaltchenko *et al.* (1999)) cannot be excluded. The BCS-like gap (see Fig. 12) together with the isotropic $B_{c2}(T)$ observed below T_N (see Fig. 13) strongly suggests that superconductivity in the low-temperature antiferromagnetic phase survives at a pillow-like Fermi surface sheet (Drechsler *et al.*, 2004) which is isolated from the influence of the lanthanide magnetism localized at other FSSs.

A remarkable anisotropy in $B_{c2}(T)$ can be seen in Fig. 13 for a well-annealed single crystal at temperatures above T_N and even in the paramagnetic region above T_M . From a comparison of this phenomenon with the much weaker and opposite anisotropy of $B_{c2}(T)$ in $\text{YNi}_2\text{B}_2\text{C}$ (see Section "Fermi Surface in Non-Magnetic Borocarbides in the Normal and Superconducting State") it can be concluded that $B_{c2}(T)$ is smaller for H parallel to $[110]$ (compared to $[001]$; see Fig. 13) because, due to crystalline electric fields, the magnetic fluctuations have larger components in the tetragonal basal plane. Further contributions to the anisotropy of $B_{c2}(T)$ may come from anisotropic Fermi surface sheet possibly contributing to the small- (or even zero-) gap superconductivity in $\text{HoNi}_2\text{B}_2\text{C}$ at temperatures above T^* as discussed above.

To summarize, it can be concluded that a multiband scenario is indispensable for understanding the rich variety of superconducting and magnetic properties in $\text{HoNi}_2\text{B}_2\text{C}$. Many of these phenomena, in particular those occurring at temperatures between T_N and T_M , are not yet well understood.

The RABiTS Approach for Second Generation (2G) High Temperature Superconductors

Introduction

In this chapter, we provide an overview of the Rolling Assisted Bi-axially Textured Substrate (RABiTS™) process for fabricating long length high temperature superconducting (HTS) wire based on the (RE)Ba₂Cu₃O_{7-x} materials ((RE)BCO) where RE is a rare earth. The RABiTS process is one of three template technologies developed for the roll-to-roll manufacturing of long length Second Generation (2G) HTS wire (Sathyamurthy *et al.*, 2016). All three processes rely on deposition of a continuous coating of a single-crystal-like oxide film on a flexible metal substrate which supports the growth of a highly, bi-axially textured YBCO film. The RABiTS process relies on a thermo-mechanical process to establish a cube texture in a metal foil upon which a series of epitaxial oxide layers are deposited, while the other two technologies rely on the deposition of textured oxide layers onto an un-textured metal substrate. All three approaches have been successfully scaled to roll-to-roll processes by multiple manufacturers and can be combined with either solution or vacuum based process for the deposition processes of the YBCO layer. The general architecture of the 2G HTS wire produced by these processes, illustrated in Fig. 1, consists of a bi-axially textured template (metal substrate and oxide buffer layers, a (RE)BCO layer and a protective Ag layer). Depending on the manufacturer and specific application, this structure may be enclosed in an electroplated copper layer or laminated between metal foils (Cu, SS, etc.) which serve as an electrical and mechanical stabilizer.

Cuprate-Based High Temperature Superconductors

The discovery of the cuprate based high temperature superconductor materials in 1987 marked the beginning of a world-wide effort to develop superconducting wires that could be used in liquid nitrogen. However, the complex structure and isotropic properties of the cuprate materials requires a near single crystal-like texture for the supercurrent to pass from grain-to grain.

The (RE)BCO-based high temperature superconductors have a perovskite-type crystal structure that contains two CuO₂ layers surrounding the RE atom, along with separate CuO chains oriented along the *b*-axis as shown in Fig. 2. The supercurrent passes through the CuO₂ planes, while the CuO chains function as charge reservoirs providing carriers to the CuO₂ planes. The large anisotropy produced from this planar CuO₂ structure results in supercurrent in the *a-b* plane being much greater than along the *c*-axis (Cooper and Gray, 1994; Jia *et al.*, 2011).

The coherence length, (ξ), which defines the spatial distance over which the paired superconducting electrons interact, of the (RE)BCO materials is only 1–4 nm in the *ab*-plane and less than 1 nm along the *c*-axis (Tinkham, 1996). As a result, minor distortions of the lattice periodicity, such as high angle grain boundaries, appear as planar defects that block the supercurrent flow between grains. Fundamental studies of the grain boundary mis-orientations by Dimos, Chaudhari and Mannhart established that a grain-to-grain mis-orientation of $<4^\circ$ was necessary to achieve a critical current approaching that of single crystals (Dimos *et al.*, 1990; Hilgenkamp and Mannhart, 2002). The studies also showed that at angles $>4^\circ$ the current decreased exponentially. Thus, it was established that the fabrication of the YBCO materials into wires could not be achieved with bulk polycrystalline materials, but required fabrication of a bi-axially textured layer of the material deposited over continuous lengths.

This understanding of the fundamental properties of the (RE)BCO materials led to the search for approaches to prepare continuous, single crystal-like substrates on which the (RE)BCO materials could be grown over continuous lengths. In 1991, Iijima, at Fujikura, developed the Ion Beam Assisted Deposition (IBAD) process which relies on the bombardment of an oxide film, during its vapor phase deposition, by an off-normal ion beam to sputter away unfavorable grain orientations, resulting in the deposition of a highly oriented, bi-axially textured oxide film on an un-textured substrate (Iijima *et al.*, 1991, 1992). Initial work focused on YSZ and Gd₂Zr₂O₇ films; however, most manufactures now use MgO films in which the bi-axial texture is established rapidly within the first 10 nm (Arendt and Foltyn, 2004; Ko *et al.*, 2007; Hanyu *et al.*, 2010). This layer is then covered with a layer of LaMnO₃ or CeO₂ which functions as a chemically compatible nucleation layer for the (RE)BCO (Paranthaman *et al.*, 2003).

A second approach to fabricating a textured template is based on an Inclined Substrate Deposition process developed by Hasegawa *et al.* of Sumitomo Electric Industries in 1996 (Hasegawa *et al.*, 1996). In this process, an oxide film, such as MgO, is deposited onto an un-textured metal tape at a slightly tilted angle resulting in a textured MgO layer, upon which a CeO₂ coating is deposited (Bauer *et al.*, 1999).

The RABiTS technology (which is the focus of this chapter) was developed by Goyal *et al.* at Oak Ridge National Laboratory in 1996 (Goyal, 2007; Norton *et al.*, 1996; Specht *et al.*, 1998). The process is based on generating a $\{001\} <100>$ cube texture in a metal substrate by conventional rolling deformation and recrystallization techniques, as the metal is converted into a thin tape. Although many cubic metals or alloys can be textured, face-centered cubic (FCC) materials such as Cu and Ni are the materials of choice since the thermo-mechanical deformation generates a sharp texture in which the cube plane is oriented parallel to the tape

Fig. 1 General architecture of 2G HTS wire consists of the textured template (substrate and buffer layers), (RE)BCO superconducting layer, protective Ag layer and encapsulating stabilizer.

Fig. 2 Perovskite-type crystal structure of the (RE)BCO superconductor.

plane and a cube edge parallel to the rolling direction. Since the (RE)BCO is not chemically compatible with the metal substrate, it is necessary to deposit a series of epitaxial oxide layers on the substrate.

The RABiTS Template Process

In the RABiTS process, a bulk metal, usually a nickel alloy, is rolled and then annealed in an inert atmosphere to achieve a sharp cube texture with an oxide free surface that supports the growth of an epitaxial buffer layer (Goyal *et al.*, 2004, 1998). A series of oxide buffer layers are then deposited epitaxially on to the textured metal surface. The process is illustrated schematically in Fig. 3. The functions of the buffer layer are to transfer the texture of the metal substrate, prevent reaction of the metal substrate with the (RE)BCO layer and provide a surface that promotes nucleation of the (RE)BCO. The composite RABiTS structure, illustrated in Fig. 4, is generally referred to as the template for the deposition of the superconducting layer (which is generally 1–3 μm thick). The ability to produce the template in long lengths (100–1000 m) with minimal defects is an essential requirement enabling today's long length 2G wire manufacturing. The composite stack is designed to provide the degree of cube texture required for the growth of the biaxially textured YBCO while also being stable and chemically compatible with the (RE)BCO at growth conditions and amenable to formation into narrow, flexible tapes.

The RABiTS Template

The basis of the RABiTS process is the creation of a thin metallic substrate, with a sharp cube texture, that supports the growth of epitaxial oxide layers. Early R&D focused on high purity Ni substrates which can be produced with near 100% cube texture. However, pure Ni is very weak when annealed, making the high temperature roll-to-roll processing a challenge. In addition, Ni is ferromagnetic resulting in a hysteretic power loss making it less attractive for alternating current applications. Thus, research efforts rapidly focused on identifying suitable nickel alloys that would meet the following substrate requirements:

- (1) A sharp cube texture in a thin substrate with lattice parameters close to those of (RE)BCO,
- (2) Sufficient yield strength at room temperature and processing temperatures,
- (3) Oxidation resistance (no native oxide formation at conditions for buffer deposition) and
- (4) Non-magnetic.

Fig. 3 Schematic illustration of the RABiTS process.

Fig. 4 Schematic cross section of an RABiTS template showing the single crystal-like metal alloy substrate and buffer layers.

The metal substrate

The choice of material for the RABiTS substrate is critical. FCC metals, such as Cu or Ni, possess a medium stacking fault energy (SFE) and form nearly single-crystal like $\{001\} \langle 100 \rangle$ foils, in which the cube axes are aligned with the principal axes of the tape, when rolled to high reductions followed by a high temperature anneal (Fig. 3). Literature on the formation of this type of texture dates to the 1920s (Goler and Sachs, 1929). Although Cu readily forms a sharp texture, it is not a useful material since it easily oxidizes under the processing conditions required for subsequent deposition of the buffer layers. Nickel is more resistant to oxidation; however, it lacks the mechanical strength required for roll-to-roll processing at elevated temperatures and, in addition, its magnetic properties produce significant ferromagnetic losses in the superconducting wire, particularly for ac applications. Thus, nickel alloys are preferred since they oxidize less easily and have higher strength at the processing temperatures.

Two Ni alloys of particular interest include NiW and NiCr (Huhne *et al.*, 2010). Both alloys form a sharp cube texture at low concentrations of W or Cr. However, even though the SFE of these alloys decreases with concentration, the ability to form a sharp cube texture deteriorates when $[W] > 5\text{--}6\text{ at\%}$ and $[Cr] > 13\text{ at\%}$ using conventional deformation and annealing processes.

Based on these requirements and suitability for supporting the epitaxial buffer growth NiW was selected as the best choice for development of the RABiTS substrate. Although the NiW alloys with a $[W] < 9.3\text{ at\%}$ are ferromagnetic, the initial work focused on a Ni-5at%W composition since it can be produced with a high cube texture using conventional rolling and annealing processes and is only weakly ferromagnetic. However, since the competing IBAD template technology is based on a non-magnetic substrate, 2G wire based on Ni-5at%W was at a competitive disadvantage in ac applications where the ferro-magnetism contributes to enhanced ac losses. As a result, Thieme at American Superconductor Corporation (AMSC) and others carried out extensive studies of the deformation mechanisms in these high concentration alloys (Sathyamurthy *et al.*, 2016). This multi-year research effort eventually led to the development of a proprietary thermo-mechanical process to that produces an excellent cube texture in the non-magnetic Ni-9at%W alloy that closely matches that in the Ni-5at%W composition.

With the optimized deformation and annealing process, a cube texture of 96%–98% is achieved over the length and width of the NiW alloy substrates with in-plane texture, $\delta\phi$, values in the range of $6.5^\circ\text{--}7^\circ$. The process is also designed to minimize the formation of other texture components, such as twins and abnormal grains, which appear as obstacles to the supercurrent flow.

An alternate approach to fabricating a textured substrate, developed by Kashima (Chubu Electric Power Co., Inc.), is based on the composite structure illustrated in Fig. 5 (Kashima *et al.*, 2012). In this approach, a non-textured metal tape, such as 316 SS or Hastelloy, is roll bonded to a thin Cu tape. The composite is then subjected to a recrystallization anneal to texture the Cu layer. A

Fig. 5 Schematic illustration of a composite RABiTS substrate.

thin Ni layer is then electro-deposited onto the Cu and inherits the texture of the Cu. The Ni layer is needed to prevent the oxidation of the Cu during the buffer deposition. The advantages of the process are that the Cu forms an extremely sharp texture and that the base metal can be selected to provide the required strength for the high temperature roll-to-roll processing. Although composite is slightly magnetic due to the Ni layer, the magnetism is partially reduced during processing as Cu slowly diffuses into the Ni layer.

The buffer layers

A variety of deposition techniques have been developed for the epitaxial deposition of the buffer layers on the NiW RABiTS substrate. These include vacuum based processes such as PLD, electron beam evaporation, MOCVD, rf and reactive sputtering and non-vacuum processes such as chemical solution deposition. Among these deposition methods, chemical solution deposition may be the most cost-effective, but reactive sputtering yields the best quality film at rates amenable to large scale roll-to-roll manufacturing.

The epitaxial buffer layers play several key functions in the RABiTS template including:

- (1) *Transfer of texture from the metal substrate to the (RE)BCO layer.* In order to transfer the texture from the alloy substrate to the HTS film, the buffer layer must be able to grow epitaxially on the bare metal surface and its lattice parameters must match closely to both the substrate and the (RE)BCO film.
- (2) *A barrier to prevent metal ion diffusion from the substrate to the (RE)BCO layer during the high temperature growth.* The superconductivity of the HTS layer can be degraded by contamination with certain metal ions (i.e., little as 3% Ni substitution in the Cu site in (RE)BCO reduces the critical temperature to below 77K) (Skakle, 1998). Thus, the buffer layer must be a barrier to cation diffusion and be continuous (no cracks) and dense to provide effective chemical separation between the alloy substrate and the HTS film at the temperatures and oxygen pressures for the YBCO growth.
- (3) *A smooth, chemically inert surface for the nucleation and growth of the (RE)BCO.* The surface of the buffer must be closely lattice matched to the (RE)BCO and provide a smooth, chemically compatible surface for the YBCO nucleation.

Ideally, a single buffer layer would fulfill these requirements; however, no material has been identified that meets all the requirements and can be grown epitaxially on a Ni alloy substrate. Thus, multiple layers, each meeting at least one of the requirements, are used.

The typical buffer layer stack on the RABiTS substrate consists of three layers as shown in Fig. 4: (1) a seed layer that replicates the bi-axial texture of the substrate, (2) a barrier layer that inhibits diffusion of the substrate constituents to the (RE)BCO layer during the high temperature processing, and (3) a cap layer that is chemically compatible with the epitaxial (RE)BCO nucleation and growth. Although a variety of potential materials can be used for the buffer stack, the most common choice, and the one used by AMSC, is a three-layer stack of $\text{Y}_2\text{O}_3/\text{YSZ}/\text{CeO}_2$ deposited by reactive sputtering.

Deposition of epitaxial oxide layers on textured NiW substrates requires an understanding and control of the oxide formations during the deposition process. The deposition of the seed layer must occur on an oxide free surface, since the presence of any Ni or W oxide disrupts the epitaxial nucleation, producing a degraded or random texture which passes through to the subsequent layers. Thus, in order to nucleate the epitaxial seed layer on the NiW substrate, the deposition must occur in a pO_2 regime where the Ni and W oxides are not thermodynamically stable ($< 10^{-14}$ mTorr for W and $< 10^{-12}$ mTorr for Ni). Yttrium (along with other materials such as cerium) forms a stable, stoichiometric Y_2O_3 phase in this pO_2 regime which can be achieved with a $\text{H}_2\text{O}/\text{H}_2$ atmosphere. It should be noted that these oxides cannot be grown on NiCr alloys since Cr oxides are stable at lower oxygen pressures than Y_2O_3 .

Although Y_2O_3 can be deposited onto a clean NiW surface under these conditions, the initial nucleation frequently results in multiple in-plane c -axis orientations. The multiple in-plane orientations can be prevented by the formation of $c(2 \times 2)$ sulfur superstructure on the surface of the NiW prior to the initial Y_2O_3 nucleation. The formation of the $c(2 \times 2)$ superstructure was initially observed by Cantoni *et al.* (2001, 2003) using reflection high energy electron diffraction (RHEED) to monitor the nucleation and growth of epitaxial oxide films on textured Ni-substrates. They established that the $c(2 \times 2)$ sulfur superstructure formed prior to the nucleation of the epitaxial oxide as S impurities in the Ni diffused to the surface while heating the sample to the deposition temperature. Fig. 6 shows RHEED patterns obtained from a cube textured Ni surface with (1) no $c(2 \times 2)$ superstructure and (2) with a $c(2 \times 2)$ S superstructure. The $c(2 \times 2)$ type superstructure functions by establishing a template which promotes a single in-plane orientation during the initial nucleation. Although the initial studies were carried out on pure Ni substrates, the same mechanism occurs in NiW alloys. In manufacturing processes, the $c(2 \times 2)$ sulfur structure is typically prepared by the introduction of a S containing gas prior to the start of the oxide deposition process rather than depending on the presence of S impurities.

Fig. 6 RHEED patterns obtained with the incident electron beam along $\langle 100 \rangle$ for (a) clean cube textured Ni substrate surface and (b) cube textured Ni substrate surface with a $c(2 \times 2)$ S superstructure. The formation of the $c(2 \times 2)$ superstructure in (b) is indicated by the arrows.

Fig. 7 TEM cross-section image of a NiW/Y₂O₃/YSZ/CeO₂ template after processing of the HTS layer. The out-of-plane ($\Delta\omega$) and in-plane ($\Delta\phi$) textures are shown for each layer. The adherent NiO-NiWO₄ formed during HTS processing.

Once the seed layer is deposited, the YSZ barrier and CeO₂ cap layers can be deposited by a variety of vacuum-based deposition techniques.

Fig. 7 shows the cross-sectional TEM image of a RABiTS template from a fully processed conductor produced by AMSC. The three buffer layers are deposited by reactive sputtering and are each ~ 75 nm thick. Typical values for the full width at half-maximum of the out-of-plane texture, $\Delta\omega$ and in-plane texture, $\Delta\phi$, for each layer are shown in **Fig. 7**. The Y₂O₃ (seed) layer replicates the texture of the Ni-W substrate. The middle YSZ (barrier) layer inhibits the diffusion of Ni and W to the (RE)BCO. The top CeO₂ (cap) layer has a texture closely matching that of the (RE)BCO layer and provides an optimized surface for the nucleation and growth of the (RE)BCO. The cross-section image in **Fig. 7** also shows the presence of a NiO-NiWO₄ layer between the Y₂O₃ and NiW. This layer forms during the conductor processing, after the preparation of the template, and is an adherent oxide that does not affect the texture or mechanical properties of the conductor.

A unique aspect of the Y₂O₃ seed layer (**Fig. 7**) is the improvement in texture, compared to the NiW substrate, which propagates through to the YSZ and the CeO₂ layers. The texture sharpening, which is unique to the PVD Y₂O₃ layer is believed to arise from lattice strain introduced during the deposition process (Cantoni *et al.*, 2009). The enhanced texture propagates through to the (RE)BCO layer significantly increasing the critical current that can be carried in the (RE)BCO layer.

Fig. 8 shows an orientation image micrograph of the CeO₂ surface of a NiW/Y₂O₃/YSZ/CeO₂ template obtained using Electron Back Scattered Diffraction. Grain boundaries with mis-orientations of $> 4^\circ$ are indicated in each image. When the in-plane and out-of-plane texture orientations are separated, it is seen that $\sim 80\%$ of the template is single crystal-like with respect to the in-plane orientation.

The ability of the oxide buffer stack to prevent diffusion of the NiW to the (RE)BCO layer is shown in **Fig. 9**. The NiW/Y₂O₃/YSZ/CeO₂ template was heated in an O₂/H₂O atmosphere at around 800°C to simulate the deposition and growth process for the (RE)BCO. The cross-section TEM and SIMS depth profile through the buffer layers, in **Fig. 9**, show that diffusion of the substrate components (Ni and W) are stopped at the YSZ layer and do not reach the (RE)BCO. It is also seen that O diffuses through the buffer stack, forming the adherent NiO-NiWO₄ layer also seen in **Fig. 7**.

A critical requirement of the RABiTS technology is the ability to produce the template in long length tapes with a consistent texture along both the length and width. In the early development of the RABiTS process, roll-to-roll x-ray analysis was used to establish that the texture was maintained uniformly across the width and length of the NiW tape. **Fig. 10** shows the pole figures

Fig. 8 Electron Back Scattered Diffraction orientation map of the CeO_2 surface of a $\text{NiW}/\text{Y}_2\text{O}_3/\text{YSZ}/\text{CeO}_2$ template showing the total mis-orientation and separated in-plane and out-of-plane mis-orientations. All grain boundary mis-orientations $>4^\circ$ are indicated.

Fig. 9 TEM cross-section of a $\text{NiW}/\text{Y}_2\text{O}_3/\text{YSZ}/\text{CeO}_2$ template (top) and the SIMS profile measured through the thickness of the buffer layers (bottom) showing the extent of diffusion of the substrate components. The sample was processed in an $^{18}\text{O}_2$ environment.

(one quarter shown) of the NiW substrate and the CeO_2 cap layer measured across the width and length of a template. The data show that there is no detectable variation in the texture of either the starting substrate or the buffer layers.

Solution based processes for the buffer deposition have also been developed (Sathyamurthy *et al.*, 2004; Knoth *et al.*, 2005; Obradors *et al.*, 2006; Cordero-Cabrera *et al.*, 2007; Bäcker *et al.*, 2019). The most successful approach, used in manufacturing by Deutsche Nanoschrift, uses a two layer stack consisting of $\text{La}_2\text{Zr}_2\text{O}_7$ and CeO_2 . The $\text{La}_2\text{Zr}_2\text{O}_7$ layer functions as both the seed and barrier layers, while the CeO_2 serves as the cap layer. The oxide layers are deposited by slot die coating using metal-organic salts such as pentanedionates of La and Zr and acetates of Ce, dissolved in propionic acid and pyrolyzed at around 1000°C in a

reducing atmosphere to prevent oxidation of the metal substrate. Although the solution-based processes are attractive for industrial coating, the NiW/La₂Zr₂O₇/CeO₂ template has not achieved the same performance in the HTS wires as the NiW/Y₂O₃/YSZ/CeO₂ template.

Roll-to-Roll Manufacturing of RABiTS-Based 2G HTS Wire

A major advantage of the RABiTS technology is the ability to produce the textured metal substrate in a wide width over long lengths. This allows the subsequent roll-to-roll processes to be carried at the same width until the strip is slit into the narrower

Fig. 12 Schematic illustration (top) of a laminated 2G wire showing the RABiTS template and (RE)BCO layer encapsulated between two metal lamina and a transverse cross-section micrograph (bottom) of a 4-mm wide cable wire.

widths required for the actual 2G conductor. In contrast, textured IBAD templates are currently produced in a maximum width of ~ 12 mm, since the IBAD texturing process has a limited width uniformity.

AMSC and Deutsche Nanoschicht are the two major companies using the RABiTS template technology for the manufacture of 2G HTS wire. The NiW alloy (both Ni-5at%W and Ni-9at%W) is produced in multi ton quantities from a conventional melt of high purity Ni and W. The basic 2G HTS wire manufacturing process used with the RABiTS template is illustrated in Fig. 11. The process starts with a wide (~ 50 mm) NiW substrate which is rolled to ~ 75 μ m and annealed to form the cube texture. The buffer layers are then deposited onto the wide strip. The (RE)BCO layer is generally deposited by a Metal Organic Deposition slot-die coating process. After the (RE) BCO layer is completed and the surface is coated with a thin Ag layer, the wide strip is slit into multiple narrower strips which are converted into the final superconducting wire. In this conversion process, a metal foil is laminated to each side of the slit tape. The lamination process results in solder fillets on each edge of the tape, producing a hermetic seal and exceptional resistance to delamination during use. By varying the composition or thickness of the metal lamina, the normal-state electrical resistance and mechanical properties of the final wire are customized for specific applications. The basic architecture of the final wire is illustrated in Fig. 12 along with a cross-sectional micrograph of an actual wire.

This process routinely produces wires with lengths of around 0.5 km with critical currents (I_c) in excess of 150 A (> 400 A/cm-w) in a 4-mm wide conductor as shown in Fig. 13. RABiTS-based wires, primarily produced by AMSC, are being used in cable and fault current limiters (FCL) projects around the world and defense applications such as shipboard degaussing cables (Sohn *et al.*, 2010; Ryu *et al.*, 2013; HTS Cable Korea, 2011; HTS Cable, 2019; HTS Ship Degaussing Cable, 2019).

Summary

When the RABiTS technology was discovered in 1996, there was considerable doubt whether the approach could be developed into a scale able manufacturing process. However, vast advances have been achieved in the development of the RABiTS template technology over the past three decades. The technology has reached the level where the templates show a near single crystal-like texture, with most grain boundaries mis-orientations being $< 4^\circ$, allowing the growth of (RE)BCO films with critical current densities almost equal to those obtained on single crystal substrates. The initial development of the RABiTS templates was limited to ferromagnetic materials which generate ac losses in many electrical applications. However, improvements in the fundamental

understanding of the deformation science of Ni alloys have enabled the development of completely non-magnetic alloys based on Ni-9at%W. These alloys now allow the RABiTS based templates to be used for a broader range of applications.

The RABiTS process has been successfully scaled for the industrial manufacturing of 2G HTS wire by AMSC and Deutsche Nanoschicht. RABiTS templates are routinely produced in nearly defect-free lengths of nearly a kilometer and widths of ~ 50 mm. Second Generation HTS wires produced with the RABiTS technology are now manufactured in lengths exceeding 0.5 km with I_c 's at 77K, self-field in excess of 400 A/cm-w. These wires are currently being used for applications in the electrical grid (electrical cables and FCL) and in various defense applications including degaussing cables for ships.

Ferrite Ceramics at Microwave Frequencies: Applications and Characterization

Jean-Luc Mattei, Alexis Chevalier, and Vincent Laur, University of Western Brittany, Brest, France

Ferrimagnetic Materials

Basic Properties of Polycrystalline Ferrites

Ferrite materials are magnetic oxides, known as ferrimagnetic materials, which are characterized by high magnetic permeability values and insulating behavior over a wide frequency range. Their high electrical resistivity make low-loss ferrimagnets the ideal basis for passive microwave components operating over a wide range of frequencies, from 1 to 100 GHz. They are needed in devices where nonreciprocal behavior is expected, or to strengthen the interaction between a device and the electromagnetic signal. Depending on the applications, either hard or soft ferrites are used.

Ferrites have the following main physical properties

- High electrical resistivity (10^5 – 10^6 MΩ m)
- Relative dielectric constant of 11–17
- Low dielectric losses (2.10^{-4} – 15.10^{-4})
- A high magnetic susceptibility
- A Curie temperature of 200–560°C
- A saturation magnetization of 80 kA/m to 400 kA/m

Ferrites are made of oxygen ions, iron ions, and other cationic metals that may be magnetic or nonmagnetic. Their electrical resistivity is high, which makes them suitable materials for use in the microwave range. Considering their magnetic properties, in particular their magnetic saturation, magnetocrystalline anisotropy and coercive field, three types of ceramics are grouped together under the heading “ferrites.” There are spinel ferrites and iron garnets (which together constitute the soft ferrite family), and hexaferrites (which make up the hard ferrite family). Both spinel and iron garnets show low coercivity and low magnetocrystalline anisotropy, whereas hard ferrites are characterized by high coercivity and high magnetocrystalline anisotropy. The ferrite crystallographic structure, for garnets as well as for spinels and hard ferrites is formed by a close-packed pattern of oxygen anions. The magnetic materials most commonly used in the microwave frequency range are polycrystalline ceramics constituted of grains. These are divided into magnetic domains (Weiss domains) separated by domain walls (Bloch walls) (Fig. 1). The magnetic moments are kept parallel with each other by the strong energy exchange. Their spontaneous direction of magnetization is on an easy magnetization axis. This makes it possible to minimize the magnetocrystalline energy, which is commonly described by an anisotropy field. Because of the finite size of the magnetic volume, demagnetizing effects appears. This second contribution to the total magnetic energy corresponds to demagnetizing fields, which are proportional to the magnetization. The subdivision into magnetic domains lowers the total energy of the grain.

Hysteresis Loops and Magnetocrystalline Anisotropy

In its initial unmagnetized state, the magnetic structure of a polycrystalline material is subdivided into randomly distributed magnetic domains (the Weiss domains), separated from each other by domain walls (Bloch walls), as illustrated in Fig. 1. The variation of the magnetization M under the effect of an applied magnetic field H can be represented by a hysteresis loop that depicts the function $M(H)$ (Fig. 2). The magnetization process is due to a combination of domain wall bowing, unpinning, displacement, and to spin rotation. More precisely, for low values of H , the volume of those domains that are the more closely oriented along the magnetic field direction expands, at the expense of the other domains, through reversible wall movement. Then, for higher values of H , expansion occurs through irreversible wall displacements. From a magnetization value close to 80% of saturation, only one magnetic domain remains. For higher values of H , spins are rotated out of their easy direction by the applied magnetic field, leading the magnetization to reach its maximum value (the saturation magnetization).

Some of the main characteristic features of a magnetic material can be deduced from its hysteresis loop: The saturation magnetization M_s , the remanent magnetization M_R , the coercive force H_C , and the anisotropy field H_A . Hard and soft magnetic materials have different typical aspects, which also depend on their texturation (Figs. 3–4).

Among the parameters that characterize a magnetic material, the anisotropy field, H_A , is one of the most relevant because it is a measure of the magnetic hardness of the material, which has a considerable impact on the addressed frequency range of applications. The fact that magnetic properties of a material depend on the crystallographic direction along which the magnetic moments are aligned is a manifestation of the magnetocrystalline anisotropy. A first well-known example is that of magnetite Fe_3O_4 , which can be magnetized along the easy $\langle 111 \rangle$ -like directions, while the magnetization is harder along the $\langle 100 \rangle$ -like directions. A second example is that of Cobalt (Co), a hard magnetic material with hexagonal structure and uniaxial magnetocrystalline anisotropy: Co can be magnetized along the $\langle 001 \rangle$ -like directions, which define the easy directions of magnetization,

Fig. 1 Polycrystalline ferrite made of grains subdivided into magnetic domains. The grains boundaries are in blue color.

Fig. 2 Hysteresis loop, and schematic representation of magnetization by domain wall movements and by spin rotation in domains. Depending on the types of applications targeted, a given magnetic material may be used in different magnetization states.

Fig. 3 Typical hysteresis loop of a soft ferrite. The inset shows how the hysteresis is closed: Remanent magnetization M_R and coercive field H_C are of the order of $M_s/50$ and $H_A/50$ or below, respectively. Low coercivity and low remanence reduce the energy loss associated with hysteresis.

but its hard directions of magnetization lie in the basal plane, along the $\langle 100 \rangle$ -like directions (Fig. 5). In any case the anisotropy field H_A is defined as the field that saturates a particle along the direction of hard magnetization. Materials that have uniaxial symmetry are not easy to demagnetize, so they are used as permanent magnets. Because the values of H_A for hard magnetic materials are typically ten times higher than those observed for spinels, spinels are referred to as soft magnetic materials. The anisotropy field H_A is a fictive field that allows to describe the anisotropy effects from the expressions of the anisotropy energy,

Fig. 4 Typical hysteresis loops of a hard ferrite measured along the easy axis of magnetization (blue line) and in the hard plane of magnetization (red line). Their respective remanent magnetizations M_R and coercive fields H_C are labeled correspondingly: -E for easy axis and -H for hard axis measurements. The function $f(A)$ represents the anisotropy field distribution deduced from the virgin curve, and H_A is the so-called anisotropy field (see main text for details).

Fig. 5 Top: Crystal structure and magnetization curves (300K) of a single crystal of Cobalt. $\langle 001 \rangle$ is the easy direction of magnetization. There are six hard directions of magnetization in the basal plane, which can be deduced by hexagonal symmetry from the hard $\langle 100 \rangle$ direction. Bottom: Crystal structure and magnetization curves (300K) of a single crystal of magnetite Fe_3O_4 (only O^{2-} ions forming a face centered cubic lattice are represented). Above 130 K, $\langle 111 \rangle$ is the easy direction of magnetization, $\langle 100 \rangle$ is the hard direction of magnetization, $\langle 110 \rangle$ is the intermediate direction of magnetization.

which is itself a function of anisotropy constants (K_1 and K_2 are the anisotropy constants of first and second order, respectively). H_A is given as follows, for the various easy directions of magnetization, as a function of K_1 :

$H_A = 2K_1/\mu_0 M_S$ for the $\langle 001 \rangle$ easy axis, $H_A = -4(3K_1 + K_2)/9\mu_0 M_S$ for the $\langle 111 \rangle$ easy axis and $H_A = 2K_1/\mu_0 M_S$ for uniaxial materials (M_S is the saturation magnetization).

Factors that influence H_A in polycrystalline ferrites mainly consist of the misalignments of the magnetic grains, the magnetostatic interaction between them, and the existence of porosity. As a consequence, it is more appropriate to define an anisotropy field distribution $f(H_A)$ instead of a single anisotropy field value. This distribution can be obtained from virgin curves of magnetization (Pfeiffer, 1990). An example of $f(H_A)$ is given in Fig. 4. The highest value of the anisotropy field corresponds to the field (named H_A) at which saturation is reached, which is when the magnetizations measured along the hard and the easy directions both reach the saturation magnetization value (Fig. 5).

Depending on the types of applications targeted, a given magnetic material may be used at different magnetization states. This is illustrated in Fig. 2. With regard to the electromagnetic devices using ferrites we should mention

nonreciprocal devices (circulators, isolators, etc.), the behavior of which is based on the anisotropic permeability of the magnetic material (for this point, see Section “Microwave Passive Components Using Ferrites”). Tunable devices such as filters, resonators, and phase shifters operate on the basis of the nonlinear electromagnetic behavior of the ferrites when submitted to a dc magnetic field. Antennas can be miniaturized by using ferrites in a demagnetized state, where the magnetic permeability is high.

Soft Ferrites: Garnets Ferrites

The chemical formula for garnets is $Me_3Fe_5O_{12}$, where Me represents either a trivalent metal, such as Y, or a combination of metal ions, such as Y–Gd or Y–Gd–Al–Co. The crystal structure is orthorhombic. Among the ferrites, garnets are recommended for operating frequencies from 0.1 to 100 GHz, where they show the lowest magnetic losses ($\Delta H < 160$ A m⁻¹ (or 20 Oe)). This family includes yttrium iron garnets, yttrium aluminum garnets (YAG), calcium vanadium garnets, yttrium gadolinium garnets (Y–Gd–G), and variants with aluminum substitutions, all of which show a remarkable degree of temperature stability over –100–200°C. They are suitable for use at moderate power level. When doping with Co or Dy, YAG are usable in high-power applications. The representative properties of some garnets are listed in Table 1.

Soft Ferrites: Spinel Ferrites

The chemical formula for spinel ferrites is $MeFe_2O_4$ where Fe is trivalent ion. Me represents either a divalent metal, or a combination of divalent metal ions, such as Mn–Zn, Ni–Zn, Ni–Al, and sometimes an association of a monovalent ion (Li^+) with a trivalent ion (Fe^{3+} , Mn^{3+}). The crystal has a closed packed cubic structure. This class of spinel ferrites splits in two subclasses, depending on the frequency range addressed. First, for frequencies lower than 1 MHz, manganese–zinc ferrites are privileged, due to their high saturation magnetization (~ 480 kA m⁻¹) and low magnetic and dielectric losses ($< 3 \cdot 10^{-4}$). However, applications above 1 MHz are not to be considered due to their low electrical resistivity. The second subclass is constituted by nickel–zinc ferrites, which are suitable for use up to 500 MHz due to their high electrical resistivity (10^6 MΩ m.) The main conductivity mechanism in spinel ferrites is caused by electron hopping between Fe^{3+} and Fe^{2+} ferrite (van Uitert, 1955). For example, the effect of Fe content on the electrical resistivity of $Ni_{0.3}Zn_{0.7}Fe_{2+\delta}O_4$ ferrites is shown in Fig. 6. Iron deficient spinel ferrites show higher resistivity than stoichiometric ones, and for this reason they are highly suitable for microwave applications. In polycrystalline ferrite, grain boundaries may also play a significant role in the electrical resistivity by limiting eddy current losses.

The representative properties of some polycrystalline spinels are listed in Table 2 and in Table 3. The variations of the anisotropy constant K_1 and that of the anisotropy field H_A for some ferrites of formula $Ni_{1-x}Zn_xFe_2O_4$ (with $K_1 < 0$) and $Ni_{1-x}Zn_xCo_{0.2}Fe_2O_4$ (with $K_1 > 0$) as a function of the Zn content are presented in Fig. 7 (a) and (b) (from Mattei et al., 2015).

Hard Ferrites: Hexaferrites

The most commonly used hexaferrites include pure and substituted barium ferrites (BaO , $6Fe_2O_3$) and strontium ferrites (SrO , $6Fe_2O_3$). The crystal structure of hexaferrite is similar to that of magnetoplumbite $PbFe_{12}O_{19}$, where the Pb ion is divalent. Their

Table 3 Common cationic substitutions for spinel ferrites, and the associated intrinsic properties at room temperature. The presented values are taken from a number of sources, and represent what are generally taken to be the correct values for these ferrites

Divalent ions	Substituted trivalent ions	Saturation magnetization (M_s , kA m^{-1})	Curie temperature (K)	Resonance linewidth (ΔH , A m^{-1})	Off resonance linewidth (ΔH_{eff} , A m^{-1})
Mg, Mn	Fe	172	593	43	0.20

Li, Mn	Fe, Ti	80–230	573–773	24–46	0.12–0.72

Fig. 6 The dependence of resistivity (ρ) on iron stoichiometry for a $\text{Ni}_{0.3}\text{Zn}_{0.7}\text{Fe}_{2+\delta}\text{O}_{4\pm}$ ferrite. Adapted from van Uitert, L.G., 1955. DC resistivity in the nickel and nickel zinc ferrite system. J. Chem. Phys. 23, 1883.

anisotropy fields are two or three orders of magnitude higher than that of spinels. The operational frequencies for the large range of compositionally modified hexaferrites extend from 22 to 110 GHz. Because of their high coercive field and saturation magnetization ($H_c \sim 350 - 400 \text{ kA m}^{-1}$, $M_s \sim 300 - 350 \text{ kA m}^{-1}$), hexaferrites can be used in magnetic recording applications and fabrication of permanent magnets. The best known are $\text{BaFe}_{12}\text{O}_{19}$ and $\text{SrFe}_{12}\text{O}_{19}$. Both are called “M-type hexaferrite,” as detailed below. They have uniaxial magnetic anisotropy, where the easy axis of magnetization is the crystallographic c-axis. Moreover, some compounds containing divalent ions, especially cobalt, have a plane of easy magnetization in the basal plane, or a cone of spontaneous magnetization at an angle between 0° and 90° with c-axis. The substitutions of Fe by Sc or In allow the anisotropy field to be lowered and the frequency range of applications accordingly extends from 4 to 40 GHz (Harris *et al.*, 2014).

Several other ferrimagnetic oxides are available that are derived from combinations of ferrite spinel ($\text{MeO-Fe}_2\text{O}_3$) M-hexaferrites ($\text{BaO-6Fe}_2\text{O}_3$) and Y-hexaferrites ($\text{Ba}_2^{2+}\text{Me}_2^{2+}\text{Fe}_{12}^{3+}\text{O}_{22}$). These are, with the nominal molecular formulae in brackets and where Me represents a divalent ion, W-hexaferrites ($\text{Ba}^{2+}\text{Me}_2^{2+}\text{Fe}_{16}^{3+}\text{O}_{27}$), Z-hexaferrites ($\text{Ba}_3^{2+}\text{Co}_2^{2+}\text{Fe}_{24}^{3+}\text{O}_{41}$), and U-hexaferrites ($\text{Ba}_4\text{Me}_2\text{Fe}_{36}\text{O}_{60}$). The representative properties of some hexaferrites are presented in Table 4.

Magnetic Permeability in the Microwave Range of Frequencies

The Permeability Tensor

Wave propagation in ferrites shows nonreciprocal properties arising from gyromagnetic effects, which are directly related to the precession movement of the magnetic moments. The complex phenomena involved are presented here in a simplified form.

Undamped precessions: From the atomic moment to the lossless ferrimagnetic material

We first consider an isolated atomic magnetic moment $\vec{\mu}$. When submitted to a DC magnetic field $\vec{H}$, the top of the magnetic moment comes to a precession movement around $\vec{H}$, described by the equation of movement: $\frac{d\vec{\mu}}{dt} = -\mu_0\gamma\vec{\mu} \times \vec{H}$, where $\gamma = 1.760810^4 \text{ s}^{-1}\text{T}^{-1}$, γ being the gyromagnetic ratio. This equation describes the precession of the magnetic moment. The source of $\vec{H}$ can be either an external bias field, an internal field (which can be a magnetocrystalline field or a demagnetizing field), or a combination of them. In the absence of an external magnetic field, a precession can be brought about by the internal magnetic field produced by the total magnetic anisotropy.

Table 4 Some room-temperature intrinsic properties for various hexaferrites

Molecular formula (abbreviation)	Easy directions of magnetization	Saturation magnetization (M_s , kA m ⁻¹)	Curie temperature (K)	Magnetocrystalline anisotropy field (H_a , kA m ⁻¹)
BaFe ₁₂ O ₁₉ (BaM)	Uniaxial (c-axis)	320	723	1396
SrFe ₁₂ O ₁₉ (SrM)	Uniaxial (c-axis)	345	728	1280
Ba ₂ Co ₂ Fe ₂₈ O ₄₆ (Co ₂ X)	Cone of magnetization	272	740	760

Note: From Pullar, R.C., 2012. Hexagonal ferrites: A review of the synthesis, properties and applications of hexaferrite ceramics. Prog. Mater. Sci. 57, 1191–1334.

Turning to the case of a ferromagnetic material constituted of an assembly of magnetic moments, the DC magnetic field is supposedly large enough to bring magnetization to saturation ($\vec{M}_s$). Because the molecular field, which represents the interaction exchange, is parallel to each magnetic moment, the previous equation is validly extended to $\frac{d\vec{M}_s}{dt} = -\mu_0\gamma\vec{M}_s \times \vec{H}$, which describes the precession of the saturation magnetization. In addition, we consider that an AC magnetic field $\vec{h}$ is applied in the plane perpendicular to $\vec{H}$. As a consequence $\vec{M}_s$ is the sum of $\vec{M}$ with a variable component $\vec{m}$: $\vec{M}_s = \vec{M} + \vec{m}$. Then, within the assumption that the transverse magnetization M_x , M_y due to $\vec{h}$ is small, and thus writing $\vec{M}_s \cong \vec{M} = \text{constant}$, the equation of motion of $\vec{M}$ can be written as (Landau, 1965; Landau and Lifshitz, 1984):

$$\frac{d\vec{M}}{dt} = -\mu_0\gamma\vec{M} \times (\vec{H} + \vec{h}) \quad (1)$$

This equation is valid for an infinite medium, where no demagnetization due to the shape of the magnetic volume needs to be taken into account, and assuming that the precession is not damped. The variable component $\vec{m}$ supposedly has the same harmonic time dependance as the field $\vec{h}$ (i.e., $e^{i\omega t}$). The relationship between $\vec{m}$ and $\vec{h}$ can be written $\vec{m} = \bar{\chi}\vec{h}$, where $\bar{\chi}$ is the tensorial relative susceptibility. Solving Eq. (1), within the hypothesis framework of $|\vec{h}| \ll |\vec{H}_{DC}|$ and $|\vec{m}| \ll |\vec{M}|$, leads to the classical formulation of the susceptibility tensor $\bar{\chi}$, according to Polder (1949), or alternatively to the Polder's relative permeability tensor $\bar{\mu} = 1 + \bar{\chi}$. Its conventional expression for a magnetic field bias $\vec{H}$ arbitrarily directed along the z-direction is

$$\bar{\mu} = \begin{bmatrix} 1 + \chi & j\kappa & 0 \\ -j\kappa & 1 + \chi & 0 \\ 0 & 0 & 1 \end{bmatrix} \quad (2)$$

where

$$\chi = \frac{\omega_0\omega_m}{(\omega_0^2 - \omega_m^2)} \quad (3a)$$

$$\kappa = \frac{\omega_m\omega}{(\omega_0^2 - \omega_m^2)} \quad (3b)$$

and with $\omega_0 = \gamma|\vec{H}|$ and $\omega_m = \gamma|\vec{M}_s|$.

$\bar{\chi}$ relies on the AC magnetic field $\vec{h}$, conveyed by the electromagnetic wave, to the dynamic magnetic moment $\vec{m}$ that was generated in the material. The set of Eqs. (2) and (3) means that the energy absorption by the material from an electromagnetic wave of pulsation ω is maximal when the static field is equal to ω_0 . The gyromagnetic pulsation ω_0 is also known as the Larmor pulsation and $f_0 = \omega_0/2\pi$ is the natural ferromagnetic resonance of the ferrite. This model describes the AC susceptibility (or permeability) of a ferromagnetic material of infinite size and magnetized at saturation. However, in real situations magnetic losses are involved. This aspect will be discussed in the next section.

In the case of a ferrimagnetic material, two magnetic sublattices are present, each of which is characterized by different magnetizations and molecular fields. This situation presents a similar problem to that of two coupled oscillators. Consequently, there are two resonance frequencies, the first lying in the far infrared, which is beyond the scope of this chapter. The general expression of the second magnetic resonance frequency of the two-sublattice model has the same form as that originally obtained for the ferromagnetic case (Wangness, 1954; Smit and Wijn, 1959).

Damped precession: A dissipating behavior

In the above section our basic assumptions were firstly that the precession movement of the magnetization was undamped, secondly that the material was magnetized at saturation, and thirdly that the material has infinite dimensions. In the most general case, at least two of these assumptions are not fulfilled. Let us first consider precession damping. Interactions take place in the magnetic material, firstly inside the system of spins itself, and secondly between the system of spins and its surroundings.

Fig. 7 Anisotropy constant K_1 (dashed line) and anisotropy field H_A (full line) for some ferrites of formula (a) $\text{Ni}_{1-x}\text{Zn}_x\text{Fe}_2\text{O}_4$ and (b) $\text{Ni}_{1-x}\text{Zn}_x\text{Co}_{0.2}\text{Fe}_2\text{O}_4$ as a function of the Zn content. Adapted from Mattei, J.-L., Guen, E. Le, Chevalier, A., Tarot, A.C., 2015. Experimental determination of magnetocrystalline anisotropy constants and saturation magnetostriction constants of Ni-Zn and Ni-Zn-Co ferrites intended to be used for antennas miniaturization. *J. Magn. Mater.* 374, 762–768.

These interactions cause a damping of the magnetization precession movement. Several phenomenological models introduced damping into the former relation (1), in order to reflect the existence of forces resulting in a sharper angle between the magnetic moment and the DC field (Fig. 8). This is described by the Landau–Lifschitz–Gilbert (L–L–G) equation (Landau and Lifshitz, 1935; Gilbert, 1955):

$$\frac{d\vec{M}}{dt} = -\mu_0\gamma\vec{M} \times (\vec{H} + \vec{h}) + \alpha\vec{M} \times \frac{d\vec{M}}{dt} \quad (4)$$

In this relation $\vec{H}$ is the total bias static magnetic field, and $\vec{h}$ is the magnetic field conveyed by the plane electromagnetic wave, with angular frequency ω . Coefficient α is a phenomenological factor that characterizes the damping behavior of the magnetic moments. The permeability tensor remains in the form expressed by relation (2). The diagonal and extradiagonal terms (χ and κ) can now be written as:

$$\chi = \frac{\Omega_0\omega_m}{(\Omega_0^2 - \omega_m^2)} \quad (5)$$

$$\kappa = \frac{\omega_m\omega}{(\Omega_0^2 - \omega_m^2)} \quad (6)$$

where the complex angular resonance frequency Ω_0 is written as:

$$\Omega_0 = \omega_0 + j\omega\alpha \quad \text{with } \omega_0 = \gamma H \quad (7)$$

The effect of damping on the diagonal (μ) and extradiagonal (κ) terms of the magnetic susceptibility tensor is shown in Fig. 9. The angular resonance frequency ω_R , which corresponds to the frequency at which μ'' and κ'' reach their maximum value, depends on the damping factor according to the relationship $\omega_R = \frac{\omega_0}{\sqrt{1+\alpha^2}}$.

The frequency dispersion of the permeability spectrum $\mu(f)$

For polycrystalline ferrites, the frequency dispersion $\mu(f)$ of the permeability spectrum can be assigned to and described by the superposition of two types of magnetizing processes, i.e., spin rotation and domain wall motion (Rado, 1953):

$$\mu(f) = \mu_s + \mu_{DW} = 1 + \chi_s + \chi_{DW}$$

Fig. 8 Precessional dynamic of magnetization, with phenomenological damping.

Fig. 9 Incidence of the damping factor α on the magnetic permeability spectra of $\mu(\omega/\omega_0) = 1 + \chi(\omega/\omega_0)$, and on $\kappa(\omega/\omega_0)$, where $\chi(\omega/\omega_0)$ and $\kappa(\omega/\omega_0)$ are given by Eq. (5) and Eq. (6), respectively, plotted in reduced units of angular frequency (ω_0 is the angular resonance frequency without damping). Real part (full lines) and imaginary part (dashed lines) of μ and κ are presented for different values of α (0.07, 0.1, 0.2, 1), as indicated in the figure.

The first contribution is given by the damped spin rotation. When derived from Eq. (5) and Eq. (7), the real part and imaginary part of spin-rotation susceptibility are described by Eqs. (8 and 9):

$$\chi'_S = \chi_S^{stat} \frac{\left[\left(1 - \frac{\omega^2}{\omega_0^2} (1 - \alpha^2) \right) \right]}{\left[\left(1 - \frac{\omega^2}{\omega_0^2} (1 + \alpha^2) \right) \right]^2 + 4\alpha^2 \frac{\omega^2}{\omega_0^2}} \quad (8)$$

$$\chi''_S = \chi_S^{stat} \frac{\omega}{\omega_0} \alpha \frac{\left[\left(1 + \frac{\omega^2}{\omega_0^2} (1 + \alpha^2) \right) \right]}{\left[\left(1 - \frac{\omega^2}{\omega_0^2} (1 + \alpha^2) \right) \right]^2 + 4\alpha^2 \frac{\omega^2}{\omega_0^2}} \quad (9)$$

These expressions include three parameters: The spin damping factor α , the natural angular resonance frequency ω_0 , and the DC spin-rotation susceptibility χ_s^{stat} .

The second contribution arises from magnetization process associated with domain-wall displacement. The real part and imaginary part of domain wall susceptibility are described by Eqs. (10) and (11), which were established from an analogy with the harmonic oscillator (Perekalina *et al.*, 1961; Mikami, 1973):

$$\chi'_{DW} = \chi_{DW}^{\text{stat}} \frac{\left(1 - \frac{\omega^2}{\omega_{DW}^2}\right)}{\left(1 - \frac{\omega^2}{\omega_{DW}^2}\right)^2 + \beta^2 \frac{\omega^2}{\omega_{WD}^2}} \quad (10)$$

$$\chi''_{DW} = \chi_{DW}^{\text{stat}} \frac{\beta \frac{\omega}{\omega_{DW}}}{\left(1 - \frac{\omega^2}{\omega_{DW}^2}\right)^2 + \beta^2 \frac{\omega^2}{\omega_{WD}^2}} \quad (11)$$

The involved parameters are the wall-damping factor β , the angular relaxation frequency ω_{DW} , and the DC wall susceptibility χ_{DW}^{stat} .

The angular frequency ω_R^{DW} where χ''_{DW} reaches its maximum value is given by the relation:

$$\omega_R^{\text{DW}} = \omega_{DW} \sqrt{\frac{1}{3} \left[1 - \frac{\beta^2}{2} + \sqrt{\left(\left(1 - \frac{\beta^2}{2} \right)^2 + 3} \right)} \right]}$$

The measured permeability of a $\text{Ni}_{0.5}\text{Zn}_{0.3}\text{Co}_{0.2}\text{In}_{0.02}\text{Fe}_{1.98}\text{O}_4$ polycrystalline material was fitted (Fig. 10) assuming that the permeability spectrum is the superposition of these two contributions to magnetization process. The first one was attributed to spin rotation, which is grain-size independent. Opposite, the second one, attributed to domain-wall motion, depends on the grain size (Goldman, 2006). It was observed by experimental means that the grain-size distribution presented two maxima, both over the single-domain grain size value. Accordingly, a satisfactory fit was obtained when, in addition to the spin-rotation contribution, two domain-wall contributions were involved.

In practice, even though the absorption peak that appears on the spectra of the imaginary parts of the permeability tensor components is well described by the Polder formulations if the magnetic body is saturated, the actual absorption peak is much broader in the case of a demagnetized state and is, moreover, shifted through higher frequency values for partially magnetized state. This is mainly due to two effects directly linked to the shape of the magnetic volume, and to its subdivision in magnetic domains, which were not yet taken into account. These points are addressed in the following section.

Shape-demagnetizing effects

When establishing Eq. (3), the strong hypothesis was made that the applied DC field intensity was high enough to cause the disappearance of the magnetic domains and the magnetic moment alignment in its direction. Consequently, the internal magnetic field was considered to be constant throughout the magnetic volume. Then, neither the shape of the sample nor its aspect ratio were taken into account. From a strict point of view, Polder's model is therefore valid only at the scale of the saturated ferrite of infinite size. However, the resonance frequency actually depends for a large part on the geometrical characteristics of the sample. In order to extend the validity of Polder's model to materials of finite size, Kittel took into account the shape-demagnetizing effects, which directly depend on the shape of the material (Kittel, 1951). Regarding the case of ideal ellipsoidal shaped material, the demagnetization contribution to the internal magnetic field for an isolated and uniformly magnetized volume is the dipolar-demagnetizing field $\vec{H}_d$, which is expressed as $\vec{H}_d = -\vec{N}\vec{M}$. $\vec{H}_d$ is in the opposite direction to the applied field. The diagonal demagnetization tensor $\vec{N}$ is defined so that its diagonal components verify $N_x + N_y + N_z = 1$. The N_i s are geometric factors, known as demagnetizing factors or demagnetization coefficients. At every magnetic core of finite dimensions, the demagnetizing field reduces the external field (except for a closed toroidal core of homogeneous full material submitted to an external field with the orthoradial symmetry, allowing the closure of the magnetic flux lines). For an ellipsoid with the static magnetic field in the z -direction, the internal field is uniform, and it can be written as $\vec{H}_i = \vec{H} + \vec{H}_d$ and Kittel's equation gives the resonance pulsation (also called: Ferrimagnetic resonance frequency (FMR)):

$$\omega_0 = 2\pi\mu_0\gamma \sqrt{\left(H + (N_x - N_z)M_z \right) \left(H + (N_y - N_z)M_z \right)} \quad (12)$$

Demagnetization coefficients are well-known for some ideal shapes of ferrites (Table 5). For example, the demagnetization factors of the sphere are the same in the three Cartesian directions: $N_x = N_y = N_z = 1/3$. Regarding Eq. (12), the FMR of a ferrite sphere will be similar to that of an infinite material, which is why sphere samples are used to extract the intrinsic properties of ferrites, such as their anisotropy field. For a flat cylinder with the z -axis perpendicular to its surface, $N_x = N_y = 0$ and $N_z = 1$. Following Eq. (12), the FMR will be lower than the one of an infinite material.

N_i coefficients can be rigorously calculated for ellipsoidal shapes, but only estimated for other shapes. The numerical values of demagnetizing factors have been calculated for ellipsoids (Osborn, 1945), for circular cylinders (Chen *et al.*, 1991), and for rectangular prisms (Aharoni, 1998).

Fig. 10 Permeability spectra of a $\text{Ni}_{0.5}\text{Zn}_{0.3}\text{Co}_{0.2}\text{In}_{0.02}\text{Fe}_{1.98}\text{O}_4$ sintered ferrite. Upper figure: Experimental values are represented by symbols. Solid lines show total permeability combined with spin rotation and domain wall motion components (black lines). Their respective contributions to the total real permeability (μ') and imaginary permeability (μ'') (both shown by black lines) are detailed in the lower figures: Spin rotation (blue lines) and domain wall motion (red and green lines).

Fig. 11 Rectangular prism with a DC field applied along z-axis.

Fig. 12 Evolution of the N_z coefficient as a function of $p = c/a$ in the case of a rectangular prism with $a = b$ (calculated from Aharoni's equations).

In the case of rectangular prisms, whose dimensions are $2a$, $2b$, and $2c$ (Fig. 11), Aharoni proposed analytical formulas that make it possible to estimate demagnetization coefficients along the three Cartesian coordinates. In general, these equations are complex. In the particular case of a square cross-section, $a = b$, the N_z coefficient can be calculated using the following equations:

$$\begin{aligned} \pi N_z = & \left(p - \frac{1}{p}\right) \ln\left(\frac{\sqrt{p^2 + 2} + 1}{\sqrt{p^2 + 2} - 1}\right) + \frac{2}{p} \ln(\sqrt{2} + 1) + p \ln\left(\frac{\sqrt{p^2 + 1} - 1}{\sqrt{p^2 + 1} + 1}\right) \\ & + 2 \arctan\left(\frac{1}{p\sqrt{p^2 + 2}}\right) + \frac{2(1 - p^2)}{3p} \sqrt{p^2 + 2} + \frac{2(1 - p^3)}{3p} - \frac{2^{3/2}}{3p} \end{aligned} \quad (13)$$

where $p = c/a$.

The evolution of the N_z coefficient of a square prism ($a = b$) as a function of shape factor p calculated using Aharoni equations is shown in Fig. 12. For low values of p , the case corresponding to a flat plate, N_z is close to 1 in accordance with Table 2. The special case of a cube ($a = c$ leading to $p = 1$) leads to a value of $1/3$, similar to the case of a sphere (Fig. 12).

For a flat cylinder, a shape that is mostly used in microwave circulators, Helszajn (2008) established relationships between the thickness of a cylinder H , its radius R , and approximate demagnetizing coefficients along the three Cartesian coordinates, as follows:

$$N_z \approx 1 - \left(\frac{H}{2R}\right) \left[1 + \left(\frac{H}{2R}\right)^2\right]^{-1/2} \quad (14)$$

$$N_x \approx N_y \approx \frac{1}{2}(1 - N_z) \quad (15)$$

As an example, for a thin disk with a height $H = 0.1$ mm and a radius $R = 1.25$ mm, these formulas give $N_z = 0.959$, $N_x = N_y = 0.02$. Such a flat cylinder gives rise to a strong demagnetizing field along the z -direction so that internal field will be lower than the applied field (Fig. 13).

An ellipsoid has the property that when a uniform DC magnetic field is applied to it, the demagnetizing field is uniform throughout the sample. In practice, however, the shape of the ferrite sample is rarely an ellipsoid, and consequently nonuniformity of the internal field is frequent. Ferromagnetic bodies with arbitrary shapes do not have uniform spatial distribution of demagnetizing fields and the N_z coefficient calculated by using Aharoni formulas is only an approximation. An example of the spatial

Fig. 13 Ferrite cylinder with a DC field applied along z-axis (radius R and thickness H).

Fig. 14 Example of the spatial distribution of the internal magnetic field for a ferrite puck polarized by an uniform external magnetic field (analysis performed by using OPERA3D packages, OPERA3D, Vector Fields. Kindlington, Oxford.).

distribution of the internal magnetic field for a ferrite puck polarized by a uniform external magnetic field is presented in **Fig. 14**. If this internal field inhomogeneity is not taken into account, it may have a detrimental impact on the operations of the device that would use such a ferrite. This will be presented in greater details below.

Analytical equations making it possible to calculate the evolution of N_z coefficient as a function of the radius in a flat cylinder of ferrite under a uniform DC magnetic field were proposed by [Helszajn \(2008\)](#). In this model, two different equations are used to calculate $N_{z,center}$ at the center of the sample and $N_{z,edge}$ at its edge ([Joseph and Schlöemann, 1965](#)). This set of equations was unified by Helszajn in order to calculate the spatial distribution of N_z in a disk of ferrite.

$$N_{z,center}(r, 0) = 1 - \frac{(H/2R)}{[1 + (1 + (H/2R)^2)]^{1/2}} - \left[\frac{3(H/2R)}{[1 + ((H/2R)^2)]^{3/2}} - \frac{3(H/2R)^3}{[1 + ((H/2R)^2)]^{5/2}} \right] \left(\frac{r}{2R} \right)^2 \quad (16)$$

$$N_{z,edge}(r, 0) = \frac{1}{2} + \left(\frac{1}{\pi} \right) \tan^{-1} \left[\left(\frac{2R}{H} \right) - \left(\frac{2r}{H} \right) \right] \quad (17)$$

$$N_{z,global}(r, 0) = (N_{z,center} - N_{z,edge}) [1 - (r/R)^4] + N_{z,edge} \quad (18)$$

Fig. 15 shows the evolution of the N_z coefficient as a function of the ratio between the distance to the center r and the radius R of a ferrite disk. This calculation was performed for a flat disk of thickness $H = 0.1$ mm and radius $R = 1.25$ mm. These results demonstrate that demagnetization coefficients are strongly inhomogeneous in such ferrite disks with a strong decrease from the center of the disk ($N_z = 0.96$) to the edge ($N_z = 0.5$).

Fig. 15 Demagnetizing factor of a flat cylinder as a function of the distance to the center r/R calculated using Eqs. (8)–(10) and compared with FE simulation.

Fig. 16 Spatial distribution of the N_z coefficient in a flat disk of ferrite calculated with FE simulator.

This variation was compared with finite element calculation. The simulation was performed for a flat ferrite disk with the same geometry ($H = 0.1$ mm, $R = 1.25$ mm) and a saturation magnetization $M_s = 23,873$ A m⁻¹ under a uniform applied static magnetic field $H_{DC} = 70,000$ A m⁻¹. The variation of N_z as a function of r/R at the midheight of the disk is shown in Fig. 16. Although the trend is similar to the model proposed by Joseph, Schlöemann, and Helzasjn, one should note that the values are slightly lower.

In reality, the situation in such ferrite samples is actually more complex than a single variation of a demagnetizing field in the plane of the disk. Fig. 16 thus shows the spatial distribution of the demagnetizing coefficient N_z parallel and perpendicular to the plane of a ferrite disk. Even for a disk with a very low thickness to height ratio (H/R), one should note a nonnegligible variation of N_z along the thickness of the disk, thus inducing a different spatial distribution of N_z at the top and the middle of the sample.

The effect of shape, and thus of the demagnetizing field, can be taken into account in the calculation of dynamic permeability by using the following equations (H_{DC} applied along z -axis):

$$\mu = 1 + \frac{\omega_m(\omega_0 + \omega_m(N_y - N_z)) + j\omega\alpha\omega_m}{(\omega_0 + \omega_m(N_x - N_z))(\omega_0 + \omega_m(N_y - N_z)) - \omega^2(1 + \alpha^2) + 2j\omega\alpha\omega_0} \quad (19a)$$

$$\kappa = \frac{\omega\omega_m}{(\omega_0 + \omega_m(N_x - N_z))(\omega_0 + \omega_m(N_y - N_z)) - \omega^2(1 + \alpha^2) + 2j\omega\alpha\omega_0} \quad (19b)$$

Fig. 17 Calculated permeability for different shapes of ferrite ($M_s = 23873 \text{ A m}^{-1}$, $\alpha = 0.1$, $H_{DC} = 70,000 \text{ A m}^{-1}$).

Fig. 18 Isolation of a LTCC circulator in the 7.5–12.5 GHz frequency band: Comparison between measurement, simulation with a uniform internal field and simulation with a nonuniform internal field.

As an example, permeability was calculated for different shapes of samples in the case of a ferrite (Fig. 17), with the following properties: $M_s = 23,873 \text{ A m}^{-1}$, $\alpha = 0.1$, $H_{DC} = 70,000 \text{ A m}^{-1}$. As $N_z = N_y = N_x$ for a sphere, calculated permeability is similar to that of an infinite ferrite (without taking into account shape effect); FMR is thus only dependent on the internal magnetic field. This consideration explains why spherical samples are used to extract the anisotropy field of ferrites. A flat sample (flat disk) leads to a lowering of FMR due to the effect of the strong demagnetizing fields. In contrast, long samples (a long cylinder) induce an increase of FMR due to the decrease of N_z coefficient compared with spherical samples. Moreover, the shape of the ferrite sample has an impact on the level of permeability at frequencies lower than the FMR. As an example, at 200 MHz, the permeability of a flat disk will be 1.53, and one of a long cylinder will be 1.29. The difference is greater than 18% and can lead to a frequency shift when such materials are used to fabricate antennas or filters.

Taking into account shape effect and magnetizing field inhomogeneity can be crucial in the modeling of ferrite-based devices. As an example, in [Thalakkatukulathil et al. \(2018\)](#), a microstrip circulator in low temperature cofired ceramics technology was designed and measured. This component uses a ferrite disk biased by a magnet and surrounded by a dielectric substrate. At first, the design was performed by considering a uniform internal field in the ferrite sample. Measurement showed that the bandwidth in which isolation level is lower than -15 dB was broader in measurement than in simulation (Fig. 18). Then, multiphysics simulation, which allows taking into account the nonuniformity of internal static magnetic field, was performed by coupling a magnetostatic analysis of the structure and an electromagnetic computation. Such analysis provides better agreement between simulation and measurement and demonstrates the possibility to consider the spatial inhomogeneity of internal static magnetic field in the ferrite sample in the design of ferrite-based devices.

Dynamic demagnetizing aspect: The Polder–Smit effect

In the case of a unsaturated magnetic volume, the interactions between the magnetic domains (Fig. 1) lead to dynamic demagnetizing effects.

This situation was studied by [Polder and Smit \(1953\)](#). The authors established that the AC field acting on the domains is not only constituted by the field associated with the electromagnetic wave, but also includes dynamic demagnetizing fields depending on the orientation of the domains, as well as to the material's shape. For a better understanding of the phenomenon, we will

Fig. 19 Depiction of the Polder-Smith effect. Adapted from Polder, D., Smit, J., 1953. Resonance phenomena in ferrites. *Rev. Mod. Phys.* 25 (1), 89–90.

consider a demagnetized ellipsoidal material, with lamellar magnetic domains, as depicted in **Fig. 19**. From domain to domain, the magnetization points in the reverse directions are called “up” and “down.” When exposed to an AC field $\vec{h}$ the “up” and “down” magnetizations will precess in opposite way. If $\vec{h}$ is perpendicular to the magnetic walls, the normal component of magnetization $\vec{m}$ is continuous and therefore no dynamic demagnetizing field exists. However, if $\vec{h}$ is parallel to the magnetic walls, then there is no continuity of the normal component of magnetization $\vec{m}$, and a dynamic demagnetizing field appears.

The intensities of the dynamic demagnetizing fields are distributed in the range $[0, M_s]$. The corresponding resonance pulsations (or frequencies) vary between $\omega_{\min} = 2\pi\mu_0\gamma H$ and $\omega_{\max} = 2\pi\mu_0\gamma(H + M_s)$. Consequently, the χ'' peak is enlarged, meaning that the absorption is generated between these two pulsations.

Modeling the dynamic permeability of polycrystalline ferrites in any magnetization state

In actual materials nonuniformity of the internal field in ferrite prevents some regions from being saturated. Therefore other formulations of the permeability tensor are necessary to accurately predict the dynamic permeability of the ferrite medium. Different empirical models have been proposed that provide formulas for the elements of $\vec{\mu}$. [Schlömman \(1970\)](#) studied the case of a demagnetized body, the magnetic domains of which were randomly distributed along the three directions. Taking into account the magnetic domains magnetized along opposite directions, the off-diagonal elements of the tensor vanish. Then a mean permeability can be calculated. On the basis of Schlömman’s model, and assuming a magnetic body constituted of up and down magnetic domains, Igarashi and Naito calculated the permeability tensor elements ([Igarashi and Naito 1977, 1981](#)). Under the hypothesis that the magnetocrystalline field is the only contribution through the DC internal field, and also assuming that the actual frequency is far from the resonance frequency, [Rado \(1953\)](#) expressed the permeability tensor elements based on a spatial average of the magnetic domains. Starting from experimental results on the measurements of permeability tensor elements, [Green and Sandy \(1974\)](#) deduced an empirical expression of the tensor, which suits with Schlömman theory. However, the first theoretical and predictive model that allowed the determination of the permeability tensor of polycrystalline ferrites regardless of their magnetization state was proposed by [Gelin and Berthou-Pichavant \(1997\)](#) and [Gelin et al. \(2005\)](#). Thereafter [Gelin and Queffelec \(2008\)](#) introduced the generalized permeability tensor model that improved accuracy in the description of the magnetic losses phenomena. This model remains the only predictive model for the permeability tensor of polycrystalline ferrites in any magnetization state ([Guennou et al., 2007](#); [Cortes et al., 2015](#); [Le Gouellec et al., 2016](#)).

Microwave Passive Components Using Ferrites

Wave Propagation in Magnetized Ferrimagnetic Materials

The aim of this section is to briefly describe the basis of physical phenomena (usually termed Faraday effect) that is exploited by nonreciprocal microwave devices, such as circulators and isolators. A wave that propagates in a parallel manner to a static field $\vec{H}$ can be represented by two contrarotating circularly polarized components. Permeabilities can then be defined for the positive and negative rotation directions. The positive direction is clockwise when viewed in the direction of $\vec{H}$.

We consider an electromagnetic wave to be linearly polarized, with the direction of propagation directed along the static field $\vec{H}$, arbitrarily assumed to go along the z-axis. The electromagnetic field $\vec{h}$ can be divided into two components with clockwise circular polarization $\vec{h}_+$ and counterclockwise circular polarization $\vec{h}_-$ around z. An effective magnetic permeability, μ^+ and μ^- respectively, is calculated for each of them ([Epstein, 1956](#)) as follows:

$$\mu^{\pm} = \mu \pm \kappa \quad (20)$$

where μ and κ are given by [Eqs. \(5\) and \(6\)](#).

Fig. 20 Plots of the real and imaginary parts of the effective magnetic permeabilities μ^+ and μ^- as a function of the reduced field (left side) and of the reduced angular frequency (right side).

Their real and imaginary parts expressed as:

$$\mu^{+'}(\omega) = 1 + \frac{\omega_m(\omega_0 - \omega)}{(\omega_0 - \omega)^2 + \alpha^2\omega^2} \quad (21a)$$

$$\mu^{+''}(\omega) = \frac{\omega_m\alpha\omega}{(\omega_0 - \omega)^2 + \alpha^2\omega^2} \quad (21b)$$

$$\mu^{-'}(\omega) = 1 + \frac{\omega_m(\omega_0 + \omega)}{(\omega_0 + \omega)^2 + \alpha^2\omega^2} \quad (21c)$$

$$\mu^{-''}(\omega) = \frac{\omega_m\alpha\omega}{(\omega_0 + \omega)^2 + \alpha^2\omega^2} \quad (21d)$$

The plots in **Fig. 20** (right side) show that $\mu^{-''}$ is very close to zero, and that $\mu^{-'}$ remains almost constant. This demonstrates that the counterclockwise polarized wave weakly interacts with the magnetic material, whereas the propagation of the clockwise polarized wave is strongly influenced by the propagating magnetic medium.

An alternative expression is often presented that gives the complex permeability as a function of the static field. Remembering that $\omega_0 = \gamma H$ and $\omega_m = \gamma M_s$, the complex permeability μ^+ can be written as follows:

$$\mu^+(H) = 1 + \frac{\omega_m(\omega_0/\gamma - H)}{(\omega_0/\gamma - H)^2 + \frac{\Delta H^2}{4}} \quad (22a)$$

$$\mu^{+''}(H) = \frac{\omega_m \frac{\Delta H}{2}}{(H - \omega_0/\gamma)^2 + \frac{\Delta H^2}{4}} \quad (23b)$$

ΔH is the gyromagnetic line width, defined as the half-width of the resonance peak $\mu^{+''}$.

Fig. 20 shows components $\mu^{+'}$ (dispersive) and $\mu^{+''}$ (dissipative) of the permeability tensor elements, as functions of the reduced applied field (H/H_0) and of the reduced applied frequency (ω/ω_0). The medium was assumed to be magnetically saturated.

The expressions for $\mu^{-'}$ and $\mu^{-''}$ are as follows:

$$\mu^{-'}(H) = 1 + \frac{\omega_m(\omega_0/\gamma + H)}{(\omega_0/\gamma + H)^2 + \frac{\Delta H^2}{4}} \quad (24a)$$

$$\mu^{-''}(H) = \frac{\omega_m \frac{\Delta H}{2}}{(H + \omega_0/\gamma)^2 + \frac{\Delta H^2}{4}} \quad (24b)$$

Microwave Magnetic Losses

In order to measure losses at ferromagnetic resonance, experiments usually consist of power absorption measurements: A constant high frequency AC field is applied simultaneously to a DC field of variable magnitude, which should be strong enough to ensure magnetic saturation. A plot of the absorbed power as a function of the DC field magnitude, at given frequency, makes it possible to obtain the resonance peak. ΔH is the peak width at half-power, and is sometimes known as the absorption peak, or linewidth. It defines the magnetic losses at frequencies close to the magnetic gyroresonance appearing when the static magnetic field value allows an in-phase precession of the magnetic moments with the electromagnetic field h . Apart from the case of microwave-absorbing materials, which is beyond the scope of this chapter, the absorption peak ΔH should be narrow. However, in a polycrystalline material the actual internal field depends on many factors: Magnetic anisotropy, magnetization state, porosity, eddy currents, and inhomogeneous demagnetization

Fig. 21 Example of antenna's length reduction allowed by the use of a magnetodielectric ferrite (the ferrite is in blue color). The operating antenna frequency is 130 MHz. Various antennas topologies were studied, the more important antenna miniaturization reached 61%. Reproduced from Kabalan A., Sharaiha A., Tarot A.-C., 2019. Enhance the impact of the magneto-dielectric materials to miniaturize a planar monopole antenna. In: Proceedings of the URSI Asia-Pacific Radio Science Conference (AP-RASC), March 9–15, 2019. doi:10.23919/URSIAP-RASC.2019.8738556.

(Alvarez *et al.*, 2010). Consequently, the broadening of ΔH is due not only to the intrinsic damping of the spins (ΔH_{int}), but it contains in addition contributions from inner demagnetizing effects (ΔH_p), linked to porosity, or more generally to a residual nonmagnetic part, and to the influence of the magnetocrystalline anisotropy field H_A . Significant contributions to line width also arise from inhomogeneous demagnetization field. An expression commonly used for the total linewidth ΔH was proposed by Schlömann (1958): $\Delta H = \Delta H_{\text{int}} + 1.5pM_s + H_A$ where ΔH_{int} is the intrinsic line width and p represents the volume fraction of nonmagnetic part. The relationship between the damping factor α and ΔH_{int} , in the case of a saturated material, is $\alpha = \gamma \frac{\Delta H}{2\omega}$ (ω being the angular frequency at which ΔH is measured). In a first approximation, $H_A = \frac{K_1}{\mu_0 M_s}$, where K_1 is the first-order magnetocrystalline anisotropy constant.

However, ΔH , as defined by the Polder model of precession close to the gyroresonance, is unable to describe the full range of experimental data. This is why a complementary means to describe the magnetic losses distant from the gyroresonance is needed: An effective peak can be extrapolated from the values of the permeability away from resonance. ΔH_{eff} is the effective linewidth of the half-power peak of a Lorentz curve fitting experimental values away from the resonance. ΔH_{eff} corresponds to the off-resonance magnetic losses, and its values are lower than that of ΔH . This point will be illustrated in Section “Characterization of Magnetized Samples”.

Antenna Miniaturization

Miniaturization of electronic devices for mobile communication has led to increasing demands for the reduction of antenna dimensions. Antenna downsizing is one of today's most important challenges for antenna designers (Skrivervik *et al.*, 2001). Antenna miniaturization for wireless communication systems was first achieved through optimizing antenna design, but no other notable breakthroughs have been reported in this domain. The use of high-permittivity substrates also allow size reduction, but causes a considerable decrease in antenna efficiency and bandwidth (Hwang *et al.*, 1995; Hansen, 1982). For applications in the low-UHF frequency band (300–862 MHz), the use of magnetodielectric substrates is expected to overcome these limitations by offering larger bandwidths and improved efficiency (Hansen and Burke, 2000; Mosallaei and Sarabandi, 2004). Indeed, it has been shown (Niamien *et al.*, 2011; Niamien *et al.*, 2014) that, although the permittivity (ϵ') increases the impact of losses, as well as the stored energy, the permeability (μ') plays the opposite role by decreasing them. As a consequence, the negative impact of ϵ' on radiation efficiency and bandwidth is counterbalanced by the positive impact of μ' . Even through at frequencies lower than 30 MHz, the contribution of the domain walls to the permeability typically induces prohibitive losses. Several solutions exist that allow this problem to be avoided: Doping by Cobalt allows domain walls pinning, the use of monodomain particles may also make it possible to limit losses.

Spinel ferrites, which have $\epsilon' > 1$ and $\mu' > 1$, together with low-loss tangents (both dielectric and magnetic), are among the best candidates for antenna downsizing (Mattei *et al.*, 2011; Huitema *et al.*, 2013; Kong *et al.*, 2013; Petrov *et al.*, 2008; Kabalan *et al.*, 2019).

Fig. 21 shows the antenna's length reduction allowed by the use of a magnetodielectric ferrite (the ferrite is in blue color). In this example the operating antenna frequency is 130 MHz. In order to preserve a light weight to the device, the ferrite material was placed only where the electrical currents were large (Kabalan *et al.*, 2019) Various antennas topologies were studied, and the more important antenna downsizing reached 61% (Fig. 21(c)).

Isolators and Circulators

Nonreciprocal devices such as circulators and isolators are among the most important applications of self-biased hexaferrites (which are magnets that remain in a magnetized state in the absence of an externally applied magnetic field) in the microwave frequency range. These devices make it possible to isolate the incoming signal from the outgoing signal in transmitter/receiver

Fig. 22 Schematic representation of signal transmission through a circulator (left-hand diagram) and an isolator (right-hand diagram). For devices such as these ones, the propagation of electromagnetic waves is different in direct (port 1 to port 2) and reverse (port 2 to port 1) directions of propagation. Adapted from Harris, V.G., Sokolov, A.S., 2019 The self-biased circulator: Ferrite materials design and process considerations. *J. Supercond. Novel Magn.* 32, 97–108.

Fig. 23 Drawing of a Y-junction circulator (exploded view in the figure to the left). The ferrite puck is magnetized at saturation by the prominent bias permanent magnet.

(Tx/Rx) modules (Fig. 22). For a device such as a circulator, the propagation of electromagnetic waves is different in direct (port 1 to port 2) and reverse (port 2 to port 1) directions of propagation. Microwave systems that use a single antenna for signals emission and reception need in turn to use a circulator.

The magnetic polarization of nonreciprocal devices can be achieved through permanent magnets, placed on both sides of the ferrite (Fig. 23). However, because doing this goes against the miniaturization and lightness objectives of modern communication applications, it is highly desirable to use self-polarized hard ferrites with a reduced remanent magnetization value near $M_R/M_S = 0.85$ (Fig. 24). The device operates then at the remanent state of the ferrite. In this field, hard ferrites show great potential for integration into nonreciprocal microwave devices at frequencies from 10 to 40 GHz (Pullar, 2012; Sakai *et al.*, 2006; Harris *et al.*, 2009).

Isolators are another example of nonreciprocal microwave devices. They are used when it is necessary to isolate the device of a high-power amplifier (Fig. 22).

Microwave Characterization Methods

In this section, we summarize some characterization methods of material properties at microwave frequency. An exhaustive review of characterization methods can be found in Chen *et al.* (2004). The electromagnetic parameters of interest for microwave applications are the complex permittivity, the initial complex permeability for demagnetized materials, the complex permeability

Fig. 24 Drawing of a self-biased Y-junction circulator. The self polarized hexaferrite puck (BaM type), placed below the microstrip-Y junction, is used at the remanence.

tensor, and the ferromagnetic linewidth for magnetized materials. Measurement methods for these parameters generally fall into two categories: (1) Resonant methods, which allow high accuracy but narrowband measurements and (2) nonresonant methods, which allow broadband measurements but low accuracy. All of them use network analyzers to measure S parameters of a measurement cell, which takes the form of a resonant cavity in the first case and a transmission line or waveguide in the second case.

Characterization of Demagnetized Samples

If the ferrite is demagnetized, then the sample shows isotropic properties and its permittivity and permeability are complex scalar quantities that can be determined from the measurements of two measured complex S parameters: The reflection coefficient S₁₁ and transmission coefficient S₂₁ (Baker-Jarvis, 2005). A coaxial transmission line (Fig. 25) and a rectangular waveguide are the broadband characterization methods most frequently used because analytical relationships exist between the S parameters, dimensions of the measurement cell, and electromagnetic parameters when samples completely fill the cross-section of the cell (Weir, 1974; Nicolson and Ross, 1970).

The coaxial transmission line method offers many advantages over the rectangular waveguide method. First, the frequency band is broader because there is no lower cut-off frequency in coaxial line for the transverse electromagnetic mode, and second, the sample's shape is well adapted to the magnetic field pattern avoiding demagnetizing effects. The usual measurement frequency band in coaxial method starts from 1 MHz (depending on the Vectorial Network Analyser sensibility) up to 18 GHz (the frequency of occurrence of the first higher-order mode in APC7 standard).

Fig. 26 shows the measured permittivity and permeability for a polycrystalline demagnetized nickel ferrite. The imaginary part of the initial permeability shows two maxima: The first, around 80 MHz, is associated with the domain wall motion, and the second, close to 1800 MHz, is the gyromagnetic resonance related to the anisotropy field H_k ($H_r = \gamma H_k$). The permittivity of ferrite is generally not dispersive and remains constant over the whole frequency band, with values ranging from 10 to 20 but generally remaining close to 15.

Characterization of Magnetized Samples

If the ferrite is magnetized, the sample shows anisotropic properties and the permeability becomes a complex tensor quantity with extradiagonal terms (the permittivity does not depend on the magnetic state of the sample and remains a scalar quantity). The nondiagonal permeability tensor is the most important property used in microwave devices to reach nonreciprocal behavior.

For saturated ferrites, the permeability is well described by the Polder's model. The gyromagnetic resonance linewidth ΔH is then the fundamental property used to describe the dynamic magnetic losses. Resonance linewidth ΔH is defined as the difference between the applied field values at which absorption is half of the maximum value. The standard method for measuring the resonance linewidth ΔH of ferrites is using resonant cavities as described in the IEC standard (IEC, 1982). This method is based on the cavity perturbation theory, which requires a sample's dimensions to be smaller than one quarter of the wavelength of the microwave radiation in the sample. This method is limited to a single frequency that corresponds to the resonant frequency of the measurement cavity (generally operating around 9.4 GHz).

Fig. 27 shows the absorption of the ferrite as a function of the applied magnetic field. ΔH is the linewidth of the Lorentzian curve along the experimental points near the resonance ($H_{dc} \approx H_r$). ΔH_{eff} is the linewidth of the Lorentzian curve along the experimental points outside the vicinity of the resonance ($H_{dc} \neq H_r$).

For partially magnetized ferrites, various characterization techniques have been developed to characterize the anisotropic properties of the materials. In the resonant method, the aim is to identify and control the direction of the microwave magnetic field in the cavity so that the corresponding component of the permeability tensor can be measured. Most resonant methods use

Fig. 25 Sketch and electromagnetic field pattern of coaxial transmission line (a, b).

Fig. 26 Measured permeability of NiFeO material from coaxial transmission line method, and its fit by spin rotation and domain wall contributions. The labels dw and sr are for domain wall and spin rotation, respectively. Spin rotation and domain wall movements contributions to the magnetization are distinguished. The total permeability is the sum of these two contributions.

cylindrical or rectangular degenerate mode cavities or a ring resonator (Ogasawara *et al.*, 1976; Krupka and Geyer, 1996). These resonant methods only work at single or several discrete frequencies and are very suitable for low-loss materials but not pertinent at the resonance frequency where the values of losses are high.

In reflection/transmission methods, it is essential to measure more than two S parameters in order to determine the three unknown electromagnetic parameters ϵ , μ , and the extradiagonal term κ . To do this, measurement cells are asymmetrically filled to present nonreciprocal behavior taking advantage of the field displacement effect in the magnetized magnetic material.

Fig. 28 shows schemes of two methods based on (1) an asymmetrically loaded rectangular waveguide (Queffelec *et al.*, 2000) and (2) an asymmetrically loaded strip line (Lezaca *et al.*, 2010, 2011). In the latter method, the measurement cell consists of an asymmetric strip line partially filled with the material to be characterized. Two identical magnetic samples are placed above and below the metal strip. Two dielectrics with different permittivity values (ϵ_1 , ϵ_2) are placed on each side of the strip line to ensure the nonreciprocal behavior of the structure ($S_{12} \neq S_{21}$) when the magnetic sample is magnetized. In the forward direction of EM wave propagation, there is a strong wave-material interaction with dielectric 1. In the backward direction, thanks to the field displacement effect, the EM wave interacts with dielectric 2. This nonreciprocal nature of the measurement cell makes it possible to determine the diagonal component μ and extradiagonal component κ of the permeability tensor. This method is based on a full-wave analysis, taking into account higher-order modes (propagated in the loaded section and evanescent in the air sections of the measurement cell). By associating specific broadband optimization it

Fig. 27 Measured magnetic losses from a cavity method at 9.4GHz. ΔH is the linewidth of the Lorentzian curve near the resonance ($H_{dc} \approx H_r$). ΔH_{eff} is the linewidth of the Lorentzian curve outside the vicinity of the resonance ($H_{dc} \neq H_r$).

is possible to find the electromagnetic parameters of the unknown material while minimizing the difference between experimental and theoretical S parameters. Experimental results (Chevalier *et al.*, 2013) of the permeability tensor component μ and κ of a garnet ferrite are shown in Fig. 29.

Ferrite Magnets: Properties and Applications

Jean-Marie Le Breton, Normandie University, UNIROUEN, INSA Rouen, CNRS, GPM, Rouen, France

A permanent magnet is a material, which once magnetized, retains its magnetization at the temperature of use. Because permanent magnets can hardly be demagnetized, they are called “hard” magnetic materials. The magnetic properties of a permanent magnet are determined by the intrinsic magnetic properties of the compounds that constitute them. In addition, they are determined by the microstructure of the material obtained, in relation with the manufacturing process.

Ferrite permanent magnets are one of the classes of permanent magnet materials. The other ones are rare-earth transition metal magnets (Nd-Fe-B and Sm-Co) and alnicos (Fe-Ni-Al type). All these classes of permanent magnet materials lead to almost all, at least most, of the technological applications.

The importance of ferrite magnets for technological applications is due to both their low price and their reasonable magnetic performances. Barium and strontium hexaferrites have been used for several decades for their hard magnetic properties. This makes the range of applications extremely wide (electric motors, loudspeaker, toys, etc.) (Van den Broek and Stuijts, 1977). Consequently, ferrite permanent magnets occupy a dominant position in permanent magnets market, and their volume share is still growing.

This chapter deals with the magnetic properties of ferrite permanent magnets. In the first section, we compare the characteristics of ferrite permanent magnets with those of the other classes of permanent magnets, and present the structural and magnetic properties of the ferromagnetic compound that determine the properties of the magnet, the $\text{SrFe}_{12}\text{O}_{19}$ compound. In the second section, emphasis is placed on the characteristics of sintered and bonded ferrite magnet materials, in relation with the magnet processing. In the third section, the main applications of ferrite permanent magnets are presented.

Ferrite Magnets: One Class of Permanent Magnets

Permanent Magnets

Permanent magnet materials

Permanent magnets materials are magnetic materials that can keep their magnetization once they are magnetized that is, submitted to a magnetic field. These materials are denoted as hard magnetic materials. Their magnetization remains stable at the temperature of use.

The magnetic behavior of a permanent magnet material can be described by its hysteresis loop. Two different loops can be drawn, $B(H)$ or $M(H)$, where H , B and M are the external magnetic field, the magnetic flux density created in the material, and the magnetization of the material, respectively.

When the permanent magnet is placed in an external magnetic field H , small regions of the material where the magnetic moments share a common direction are created, forming magnetic domains. The polarization of the magnetic domains creates a magnetization M at the macroscopic scale. This results into the apparition in the material of a magnetic flux density B , which is related to M according to the following relation:

$$B = \mu_0(H + M)$$

Once all the magnetic domains are polarized in the same direction as that of the external magnetic field H , the maximum value of the magnetization is obtained. This value is the saturation magnetization M_s of the magnet.

When the external magnetic field is suppressed, the permanent magnet keeps a residual magnetization, which corresponds to the remnant magnetization M_r of the magnet. In the case of a perfect magnet, one would have $M_r = M_s$. In real magnets, M_r is slightly lower than M_s , due to the presence of structural defects and/or imperfect alignment of the magnetic domains.

The $M(H)$ and $B(H)$ curves are denoted hysteresis loops. These curves are shown in Fig. 1.

A wide variety of permanent magnet materials exist, for various applications. The different classes of permanent magnet materials have various properties. Some permanent magnets are ceramic, some are metallic.

Permanent magnets can be ceramic or metallic materials. They are characterized by their macroscopic (or extrinsic) magnetic properties: remnant induction field B_r , coercive field H_c (for a $\mu_0 M(H)$ loop) or BH_c (for a $B(H)$ loop), maximum energy field $(BH)_{\max}$. These properties are related to the intrinsic magnetic properties of the magnetic phases that are constitutive of the magnet: saturation magnetization M_s , anisotropy field H_A , Curie temperature T_C . The magnet properties also depend on the microstructure of the magnet: grain size and shape. Moreover, the mechanic and physico-chemical properties of the magnets strongly influence their applications.

Four families of permanent magnet materials lead to most of the applications on the market. These families are alnicos, hard ferrites, samarium-cobalt magnets and neodymium-iron-boron magnets. Other materials exist, such as martensitic hard steels, manganese-aluminum-carbon alloys, or micropowder-based magnets. However, their applications are very limited, being restricted to specific use.

Fig. 1 Typical B(H) and M(H) hysteresis loops of a permanent ferrite magnet. For sake of clarity, the $\mu_0 M(H)$ loop is shown instead of M(H) loop, as it can be superimposed to the B(H) loop. The typical magnetic properties of a permanent magnet (remnant induction B_r , coercive field H_c and maximum energy product $(BH)_{\max}$) are evidenced in the figure.

Permanent magnet properties

Three characteristics corresponding to three magnetic properties determine the permanent magnet behavior. These parameters, that determine the choice made by the user for a given application, are all displayed in the second quadrant of the hysteresis loop. The corresponding curves are called the demagnetization curves. They are shown in [Fig. 2](#):

- the remnant induction B_r (obtained from the B(H) loop), which represents the residual induction in closed circuit, is an indication of the potential power of the magnet;
- the coercive field of magnetization H_c (obtained from the M(H) loop) which is the demagnetizing field canceling the magnetization M , is an indication of the stability of the magnet;
- the maximum energy density $(BH)_{\max}$ (obtained from the B(H) loop), which is the maximum value of the volume energy product (BH) of the magnet; it corresponds to the optimal operating point of the magnet.

The different types of magnets can be classified according to the values of B_r , H_c and $(BH)_{\max}$. Typical values of these parameters are given in [Table 1](#).

The maximum operating temperature $T_{\max}$ of a magnet is determined by its Curie temperature T_C . The Curie temperature is the temperature at which the magnetic order is broken by the thermal agitation. The corresponding values of T_C are also reported in [Table 1](#).

A comparison of the magnetic properties of the different classes of permanent magnet materials is made in [Figs. 3](#) and [4](#). Ferrite magnets have the lowest remnant induction of permanent magnets, but their coercive field is comparable to that of Sm-Co magnets ([Fig. 3](#)). Although ferrite magnets have a low maximum energy product, their operating temperature is higher than that of Nd-Fe-B magnets ([Fig. 4](#)).

The volume production of ferrite magnets makes them the most produced and most used magnets worldwide. This is due to the following reasons:

- the raw materials are not rare nor strategic;
- these materials are low cost;
- the obtained magnetic properties allowed to develop numerous applications;
- they are corrosion resistant and chemically stable in aggressive environments.

These properties make ferrite magnets appropriate for outdoor applications, and thus well suited for high volume production. One can find ferrite magnets in almost all industries: power generation, automotive, aerospace, electronic goods, military and defense ([Goldman, 2006](#)).

Fig. 2 Typical demagnetizing curves for a ferrite permanent magnet.

Table 1 Typical values of the main magnetic properties of different classes of magnets. The values of B_r , H_c and $(BH)_{\max}$ are given at room temperature. $T_{\max}$ correspond to the maximum temperature of use of the magnets

	B_r (T)	H_c ($\text{kA} \cdot \text{m}^{-1}$)	$(BH)_{\max}$ ($\text{kJ} \cdot \text{m}^{-3}$)	T_c ($^{\circ}\text{C}$)	$T_{\max}$ ($^{\circ}\text{C}$)
Alnico	1.1–1.3	64–103	35.8–43.8	740–860	450–540
Ferrite	0.38–0.46	200–400	25.5–40.6	450–460	250–300
Sm–Co (SmCo_5)	0.82–0.87	960–1600	135.3–151.2	700–750	250
Sm–Co ($\text{Sm}_2\text{Co}_{17}$)	0.92–1.16	490–790	159.1–254.6	800–850	450–550
Nd–Fe–B ($\text{Nd}_2\text{Fe}_{14}\text{B}$)	1.0–1.3	880–1990	199.0–310.3	310–330	80–180

Permanent magnet market

Because raw materials used to manufacture ferrite permanent magnets are quite inexpensive compared to the other types of permanent magnets, especially rare-earth magnets, ferrite magnets are the cheapest magnets among all permanent magnet materials.

The excellent chemical stability of ferrite magnets makes them to be very well suited for high volume production such as generators, motors and loudspeakers. Consequently, low production cost and high availability of ferrite magnets make them occupy a dominant position in permanent magnets market.

The global permanent magnets market size was valued at USD19.23 billion in 2018 (Research and Markets, 2019). It is estimated to witness a compound annual growth rate of 8.3% from 2019 to 2025 (Goldman, 2006). In permanent magnets market, the volume share of ferrite magnets reached 81.1% in 2018 (Reports and Data, 2019).

Fig. 4 Maximum energy product vs operating temperature for the different types of permanent magnet materials.

Today, the demand for permanent magnets is driven by the increasing production of electric vehicles, rising wind energy installations, and rapidly growing robotics industry. Over the coming years, an increasing application of permanent magnets is expected in automobiles to reduce dependency on fuel as well as to enhance engine power. Other future key applications of permanent magnets are energy sector and direct-drive generators. All these applications should increase the market growth over the forecast period. In this context, the ceramic ferrite magnets market is projected to register a compound annual growth rate of 6.8% in terms of value, from 2019 to reach USD12.73 Billion by 2026 (Reports and Data, 2019).

Hexaferrite Materials

Hexaferrite material exists in a natural state as lead ferrite. It has been discovered in the 1930s. Its chemical formula being $\text{PbFe}_{12}\text{O}_{19}$, it has been called magnetoplumbite. In ferrite magnets, lead is replaced:

- by barium, to obtain materials with high remnant induction field,
- by strontium, to obtain materials with high coercive field.

Ferrite permanent magnets materials were developed at the beginning of the 1950s, in the Philips Society (Went *et al.*, 1952). $\text{BaFe}_{12}\text{O}_{19}$ was introduced under the trade name Ferroxdure (Went *et al.*, 1952). An improved composition containing strontium instead of barium has been introduced for applications like permanent magnets.

Although ferrite magnets are well known for seventy years, they have been and they are still the object of an intense research, in order to increase their magnetic properties. In fact, any improvement of these properties can have significant economic consequences in relation with specific applications. This has been the case almost twenty years ago with the production of La-Co doped ferrite magnets (Taguchi *et al.*, 1996, 2000; Kools *et al.*, 2000, 2002; Grössinger *et al.*, 2000; Le Breton *et al.*, 2002, 2004; Lechevallier *et al.*, 2003, 2004; Tenaud *et al.*, 2004).

The magnetic properties of ferrite magnets are due to the intrinsic magnetic properties of the $\text{SrFe}_{12}\text{O}_{19}$ M-type hexagonal phase.

M-type hexagonal ferrites are compounds with a hexagonal structure of the magnetoplumbite $\text{PbFe}_{12}\text{O}_{19}$ type ($\text{P6}_3/\text{mmm}$ space group). The lattice parameters of the hexagonal structure are:

- $a = 0.587 \text{ nm}$ and $c = 2.301 \text{ nm}$ for $\text{PbFe}_{12}\text{O}_{19}$;
- $a = 0.588 \text{ nm}$ and $c = 2.305 \text{ nm}$ for $\text{SrFe}_{12}\text{O}_{19}$;
- $a = 0.589 \text{ nm}$ and $c = 2.319 \text{ nm}$ for $\text{BaFe}_{12}\text{O}_{19}$.

The structure of the hexagonal ferrites is derived from a stacking of close-packed oxygen/barium or strontium layers along the hexagonal c-axis with an ordering sequence of spinel (S) two-layer building units $(\text{Fe}_6\text{O}_8)^{2+}$ and three layer (R) blocks $(\text{SrFe}_6\text{O}_{11})^{2-}$ (Fig. 5). Combination of RS gives the building motif of the magnetoplumbite M-type ferrite $\text{SrFe}_{12}\text{O}_{19}$ (Kojima, 1982).

The unit cell of the $\text{SrFe}_{12}\text{O}_{19}$ structure contains two formula units that is, 2Sr^{2+} ions, 24Fe^{3+} ions and 38O^{2-} ions. Fe^{3+} ions occupy five different sites, whose geometry corresponds to the arrangement of the O^{2-} nearest neighbors around the Fe^{3+} ion: three octahedral (namely 12k, $4f_2$ and $2a$), one tetrahedral ($4f_1$) and one bipyramidal ($2b$). These five Fe sites, together with the Sr site, are displayed in Fig. 5.

Fig. 5 Unit cell crystal structure of the hexagonal M-type phase. The Sr site and the five Fe sites are displayed. Adapted from Lechevallier, L., Le Breton, J.-M., Morel, A., Tenaud, P., 2008. *Journal of Physics: Condensed Matter* 20, 175203.

The uniaxial magneto-crystalline anisotropy of Fe^{3+} in M-type hexagonal ferrite is one of the origins of the hard magnetic properties of this material.

Some typical physical properties of the $\text{SrFe}_{12}\text{O}_{19}$ hexaferrite are:

- density 5000 kg m^{-3} ;
- resistivity $10^4 \Omega \text{ m}$;
- thermal conductivity $5.5 \text{ W m}^{-1} \text{ K}^{-1}$.

Ferrite Magnet Materials

Magnetic Properties of Ferrite Magnets

The macroscopic magnetic properties of ferrite magnets (H_c , B_r , $(BH)_{\text{max}}$) are related to the fundamental intrinsic magnetic properties of the hexaferrite $\text{SrFe}_{12}\text{O}_{19}$ compound. The intrinsic magnetic properties are:

- Curie temperature $T_C = 735\text{K}$;
- room temperature saturation magnetization $M_s = 380 \text{ kA m}^{-1}$;
- room temperature anisotropy field $H_A = 1500 \text{ kA m}^{-1}$.

In the last 20 years, numerous studies have been made to improve the magnetic properties of ferrite magnets through the improvement of the intrinsic magnetic properties of the $\text{SrFe}_{12}\text{O}_{19}$ phase. A significant improvement has been obtained when Sr and Fe were partially substituted by different cations like La–Co (Kools *et al.*, 2002; Tenaud *et al.*, 2004) or Zr–Zn (Iqbal *et al.*, 2009).

The combined substitution of La^{3+} in the Sr^{2+} site and Co^{2+} in Fe^{3+} sites lead to compositions $\text{Sr}_{1-x}\text{La}_x\text{Fe}_{12-x}\text{Co}_x\text{O}_{19}$ (Taguchi *et al.*, 2000; Kools *et al.*, 2000). These improvements are related to the increase of the intrinsic magnetic properties of the modified M-type phase, in particular to a drastic change of the magneto-crystalline anisotropy field up to 1850 kA m^{-1} (Grössinger *et al.*, 2000). It is well known that the presence of La atoms induces an increase of the magnetocrystalline anisotropy (Lotgering, 1974). This can be related to the change of the valence state of iron ions in the 2a site from Fe^{3+} to Fe^{2+} due to the introduction of La^{3+} ion instead of Sr^{2+} ion (Lotgering, 1974; Sauer *et al.*, 1978), to compensate for the excess of positive charges.

In the case of ferrite magnets, the high density of the materials results in both high remanence and sufficient mechanical strength. With the aim to obtain a high coercivity, a small grain size is needed (about $1 \mu\text{m}$) and a narrow grain size distribution

Fig. 6 The manufacture of ferrite magnets: the different steps corresponding to the processes used.

must be attained. The conventional method to obtain $\text{BaFe}_{12}\text{O}_{19}$ or $\text{SrFe}_{12}\text{O}_{19}$ hexaferrite materials is a solid state process, i.e., high temperature calcination of a mixture of $\alpha\text{-Fe}_2\text{O}_3$ and BaCO_3 or SrCO_3 .

The magnetic properties of ferrite magnets are determined by the intrinsic magnetic properties of the compounds they are based on. Their magnetic properties also strongly depend on the microstructure, which is intimately related to the manufacturing process.

Materials Processing

The different steps of the manufacture of ferrite type magnets (both sintered and bonded magnets), depending on the processes used, are shown in **Fig. 6**. These processes are used to obtain isotropic sintered hard ferrites, anisotropic sintered hard ferrites, isotropic bonded hard ferrites or anisotropic bonded hard ferrites.

Sintered Hard Ferrites

Ceramic process

Sintered hard ferrites are obtained according to a ceramic process. In this process, raw materials (iron oxide and barium or strontium carbonate powders) are mixed with the required proportions. The mixed powder is then sintered in a high temperature furnace (1200–1300°C), to allow the raw materials to react according to the following reactions:

The obtained material is then milled in humid phase. The use of attrition milling allows obtaining micrometer-sized grains. Because this size corresponds to the mean size of the Weiss domains, the obtained grains are single domain. These powders are disaggregated and can be dry- or wet-pressed. Shaping is obtained by pressing or extrusion.

Hard ferrites offer the possibility to make oriented pressing. Ferrite crystals have an easy-axis of magnetization due to their hexagonal structure. This allows to orientate the crystals in a magnetic field during shaping, and thus to obtain materials with improved magnetic properties in the easy-axis direction. Only the single domain crystals that have a certain degree of freedom compared with the other grains can be orientated.

According to the actual milling process techniques, an orientation level of more than 90% can be obtained, which induces an increase of the remnant magnetization. As their magnetic properties are not the same in all directions, the obtained ferrites are denoted as “anisotropic” ferrites. If no magnetic field is applied during shaping, the obtained ferrites are “isotropic” ferrites.

Fig. 7 Typical temperature evolution of the demagnetizing $B(H)$ curve of a sintered hard ferrite.

After shaping, sintering at temperatures of the order of 1200°C allows to obtain a densification of 90%–95%. During sintering, the dimensions of the magnets can decrease significantly. This phenomenon is denoted as shrinkage.

- (1) In the case of anisotropic ferrites, the shrinkage is anisotropic:
 - (a) a 30% shrinkage is observed in the direction of the orientation of the domains;
 - (b) a 15% shrinkage is observed in the perpendicular direction.
- (2) In the case of isotropic ferrites, the shrinkage is isotropic, from 20% to 22%.

Current grinding techniques make it possible to obtain a finer microstructure after sintering. This gives the magnet a higher coercivity.

Considering the high hardness of the ferrite material (6.5 on the Mohs scale), finishing is done by grinding with diamond grinding wheels. This allows to eliminate the asperities due to the manufacturing process. Tolerances of up to $2/100$ mm on the rectified faces can be obtained.

According to the problems encountered, related to the handling of magnetic parts during assembly, most parts are delivered unmagnetized. The magnetization is then carried out after assembly.

Properties of sintered ferrites

These properties, which are those of the obtained material, interest the user more particularly.

Chemical stability

Because sintered hard ferrites are ceramics, they are chemically stable. They are hardly dissolved and cannot be attacked by strong acids.

Their stability in time is unlimited. Indeed, the elements entering the chemical formula have saturated valence states at their most stable levels. No oxidation in the air is possible. Therefore, their magnetic properties do not degrade with time.

The chemical stability of sintered hard ferrites is the main advantage of these magnets.

Temperature coefficients

Temperature has a great influence on the properties of sintered hard ferrites. As the temperature increases, the remnant induction decreases and the magnet loses power. However, its coercive field increases and it gains stability.

The variations of the magnetic properties are typically:

- (1) remanent induction B_r : $0.2\% \text{ K}^{-1}$
- (2) coercive field H_c :
 - (a) $0.95 \text{ kA m}^{-1} \text{ K}^{-1}$ for strontium ferrite
 - (b) $0.80 \text{ kA m}^{-1} \text{ K}^{-1}$ for barium ferrite

Fig. 7 shows the typical temperature evolution of the demagnetizing $B(H)$ curve of a sintered hard ferrite.

In order to use the ferrite magnet at temperatures below 0°C , a higher coercive field than necessary at 25°C should be provided so that the operating point of the magnet remains at above the elbow of the demagnetization curve. This allows to avoid irreversible partial demagnetization of the magnet.

Dispersion of magnetic and mechanical values

The observed variations come mainly from the manufacturing process.

Table 2 Magnetic properties of high-end anisotropic sintered ferrites ($K=535$)

	B_r (mT)	H_c (kA m ⁻¹)	BH_c (kA m ⁻¹)	$(BH)_{max}$ (kJ m ⁻³)
High coercivity ferrite	385	360	285	27.3
High remanence ferrite	420	270	260	32.8

When sintering at 1200°C, the variations in the maximum temperature in industrial furnaces are of the order of $\pm 10^\circ\text{C}$. Magnetic values are sensitive to such variations. Indeed, for a variation of $+10^\circ\text{C}$ in the furnace, a variation of B_r of $+5$ mT and a variation of H_c of -12 kA m⁻¹ are observed.

During pressing, the pressed densities are dispersed. This results in a dispersion of the magnetic properties after firing. The variations for the raw parts after firing are of the order of 2.5% for B_r and 5% for H_c . The manufacturer can thus guarantee minimum values only. The automation of pressing and sintering makes it possible to reduce the dispersion of these values. This is due to the use of computerized presses and furnaces to maintain more homogeneous temperatures. The resulting part will thus be better densified and smaller.

For the same reasons, the mechanical tolerances of the raw parts of firing are about 2% due to shrinkage that the parts undergo during the densification. Thus, for a variation of $+10^\circ\text{C}$ in the oven, a variation of $+0.5\%$ is obtained for the shrinkage.

In practice, the variation of shrinkage (and therefore of the surface of the pieces) and the variation of B_r are counterbalanced to give a roughly constant flux since $\Phi = BS$.

Quality coefficient

The following quality coefficient K can be determined to characterize a given ferrite material:

$$K = B_r + 0.4H_c$$

where B_r is expressed in mT and H_c in kA m⁻¹.

The K coefficients for the range of ferrite grades are between 450 and 535. The magnetic properties and the demagnetization curves of the $K = 535$ grade are given in [Table 2](#).

Isotropic ferrites

In this type of magnets, the magnetic domains are randomly oriented. In a given direction, the remanence is almost equal to half the remanence obtained in anisotropic ferrite. These materials are therefore particularly suitable for applications for which high magnetic values are not essential or where isotropic magnetic properties are required.

The simplified manufacturing process ([Fig. 6](#)) makes these magnets particularly inexpensive. Their magnetic, electrical and physical properties are summarized in [Table 3](#).

Anisotropic ferrites

Anisotropic ferrite magnets are the most common type of ferrite magnets. Their applications are numerous. In such magnets, the orientation of the magnetic domains in a given direction makes it possible to obtain high values of the remnant induction B_r in the direction of magnetization, between 350 and 450 mT.

High remanence materials

This category includes:

- barium ferrites characterized by a relatively weak H_c coercive field, of about 150 kA m⁻¹;
- strontium ferrites characterized by an average coercive field H_c of about 250 kA m⁻¹.

The magnetic properties of a number of industrial grades are given in [Table 4](#).

High coercivity materials

These materials have a coercive field H_c of 300–500 kA m⁻¹. They are made of strontium ferrites with more or less significant additions of aluminum oxide or chromium oxide which make it possible to adjust the value of the coercive field.

The magnetic properties of a number of industrial grades are given in [Table 5](#). It should be noted that a strong coercive field can generally only be obtained at the expense of remanence.

Other ceramic materials

There are other types of ferrites that can be magnets, having magnetic properties equivalent to those of hard materials. In the ternary FeO–Fe₂O₃–BaO diagram a certain number of defined compounds have been highlighted: B, M, S, W, Y, Z. In particular, the W phase of BaFe₁₈O₂₇ composition has a magnetization saturation higher by 10%–15% than that of the BaFe₁₂O₁₉ phase. However, because of the difficulty in obtaining a pure compound, this ferrite is not industrialized.

Table 3 Room temperature magnetic properties of isotropic sintered ferrites

Magnetic property	Typical value
remnant induction B_r	220 mT
coercive field H_c	220 kA m ⁻¹
coercive field BH_c	135 kA m ⁻¹
energy density $(BH)_{\max}$	7.6 kJ m ⁻³
B_r temperature coefficient (– 4°C to 200°C)	– 0.2 (%/K)
H_c temperature coefficient (– 40°C to 200°C)	+ 0.4 (%/K)
saturation field H_{sat}	800 kA m ⁻¹
Curie temperature	450°C

Table 4 Typical magnetic properties of high remanence anisotropic sintered ferrites

	B_r (mT)	H_c (kA m ⁻¹)	BH_c (kA m ⁻¹)	$(BH)_{\max}$ (kJ m ⁻³)
Barium ferrite	400	165	160	29.5
Strontium ferrites	420	240	225	33.0
	410	275	265	41.5
	390	275	265	28.5

Table 5 Magnetic properties of high coercivity anisotropic sintered ferrites

	B_r (mT)	H_c (kA m ⁻¹)	BH_c (kA m ⁻¹)	$(BH)_{\max}$ (kJ m ⁻³)
Strontium ferrites	380	320	280	27.0
	340	335	265	21.5
	260	530	180	11.0

It is also possible to replace strontium and barium with elements such as lanthanum, or lanthanum-calcium mixtures. The magnetic properties of the materials obtained are nevertheless slightly lower than the magnetic properties of strontium or barium ferrites, the too high cost of the raw materials makes industrialization unprofitable.

However, it has been shown that the simultaneous substitution of lanthanum for strontium and iron for cobalt leads to new magnets, which result in high coercivity materials without loss of remanence (Taguchi *et al.*, 1996, 2000; Kools *et al.*, 2000, 2002; Grössinger *et al.*, 2000; Le Breton *et al.*, 2002, 2004; Lechevallier *et al.*, 2003, 2004; Tenaud *et al.*, 2004). Despite the cost of raw materials, the improvement of magnetic properties is significant and led to the industrialization of the material. These new shades of magnets are available on the market.

Bonded Ferrites

Manufacturing process

Bonded ferrites are made from ferrite powder (after presintering and dry milling) mixed with bonding agents by conventional methods in the plastics industry: extrusion, injection molding, rolling (Fig. 6).

It is possible to carry out:

- flexible magnets when the binding agent is a flexible thermoplastic;
- rigid magnets when thermosetting resins are used.

As for the sintered magnets, it is possible to obtain a magnetic anisotropy during shaping:

- by applying a magnetic field;
- or by rolling when making magnets in the form of strips or ribbons.

The manufacturing process of the bonded ferrite magnets allows the production of complex shapes, with tight tolerances. The bonded magnets can thus be folded or cut.

Magnetic properties

In a bonded ferrite magnet, the mass content of the ferrite powder can vary from 75% to 94% depending on the qualities. The density of the obtained magnet thus varies between 2500 and 3900 kg m⁻³, which is significantly lower than that of a sintered magnet. The magnetic properties of bonded ferrite magnets depend largely on the density.

Table 6 summarizes the main magnetic properties of some bonded magnets.

Table 6 Magnetic properties of some bonded ferrite magnets

	B_r (mT)	H_c (kA m ⁻¹)	BH_c (kA m ⁻¹)	$(BH)_{max}$ (kJ m ⁻³)	density (kg m ⁻³)
Anisotropic rigid magnet	240	240	175	11	3500
Isotropic rigid magnet	80	190	58	0.9	2500
	155	190	104	4.4	3900
Isotropic flexible magnet	145	190	96	3.2	3700

The dimensional tolerances without machining are of the order of $\pm 0.5\%$ for rigid magnets and $\pm 1\%$ for soft magnets.

The chemical and physical properties of the magnet are mainly related to the quality of the binding agent and to the density of the ferrite powder. In the case of bonded ferrite magnets, the chemical stability of the magnet is that of the elastomer or that of the resin. If these magnets are resistant to contact with water and mineral oils, they are quickly attacked by conventional organic solvents such as acetone, carbon tetrachloride and toluol.

Maximum operating temperatures do not exceed 100°C.

Bonded ferrite magnets are little fragile materials, unlike sintered magnets. The breaking strength is guaranteed from 30 to 150 MPa depending on the grade. These variations depend on both the binding agent and the ferrite filler.

Applications of Ferrite Permanent Magnets

Because of both their high chemical stability and their low production costs, ferrite permanent magnets remain the most used magnets today (Kramer *et al.*, 2012). They are used, often in large series, in a large number of applications where cost control remains an essential element in relation to magnetic performance. Thus, ferrite permanent magnets are used for applications when high flux density or small size are not required (Petrov and Pyrhonen, 2013). For such applications, they can be used instead of more powerful magnets with higher cost, such as rare-earth magnets.

Due to their low production costs, ferrite permanent magnets are present in a wide variety of every day life applications. They are mainly present in the motors and actuators used

- in domestic applications:
 - air conditioning system, compressor, washing machine, dryer, refrigerator, microwaves oven (rotation of the tray and fan), blender, food mixer, vacuum cleaner, hair dryer, hand dryer, electric razor, electric toothbrush, lifting pumps...
- in audio and video applications:
 - video camera (zoom, focus, tape scroll, read head motors), laser disc loader, turntables, video tape recorder (tape drive or tape drive motors), vinyl record turntables...
- in secretarial office:
 - many engines on computers, printers, photocopiers, fax...
- in automotive applications:
 - fuel pump, ABS pump, electric window regulator, electric seat, sunroof, fan, wiper, active suspension, braking, starter, door locks, air bag sensors, oil level sensors, solenoid valve sensors regulating air circulation, exhaust gas...
- in portable tools:
 - drills, screwdrivers, jigsaws, chainsaws, electric hammers, clippers...
- in medical field:
 - blood circulation pump motor, Magnetic Resonance Imaging apparatus motors, medical bed elevation motors...

Ferrite magnets are found in generators: wave power, wind turbines, turbo generators (Goldman, 2006).

Also, ferrite magnets can be found in loudspeaker coils, microphones and headphones.

Ferrites

Key Properties

Since their commercial introduction in 1948 by Philips, soft ferrites have found widespread use in electronic applications as inductor or transformer cores, because of their high resistivity in comparison to metallic soft-magnetic materials. This makes soft-magnetic ferrites considerably better suited for applications at frequencies ≥ 10 kHz. Soft-magnetic ferrites belong to the class of ferrites that have a cubic, spinel lattice structure. These ferrites have the structural formula MeFe_2O_4 with Me being a divalent metal ion from the 3d transition elements: manganese, iron, cobalt, nickel, copper, zinc, or combinations of these. In addition, also other ions such as Li^+ , Mg^{2+} , Cr^{3+} , Ti^{4+} , or Sb^{5+} can be incorporated in the spinel lattice. There is also a class of soft-magnetic ferrites with a hexagonal crystal structure, which has soft-magnetic properties. However, this class of soft ferrites has found limited application thus far (Kimura, 2012), and is not treated here. The reader is referred to the treatise by Smit and Wijn (1959).

The spinel-type lattice structure characterizing the conventionally applied ferrites is depicted in Fig. 1. This lattice structure has a lattice parameter a in the range 8.30–8.50 Å depending on the composition of the ferrite (Smit and Wijn, 1959). In the unit cell, of which $\frac{1}{4}$ is drawn in detail in Fig. 1, the oxygen ions (O in Fig. 1) form a close-packed face-centered cubic lattice. There are 64 possible tetrahedral (or A) and 32 possible octahedral (or B) interstices or sites in which metal ions can be incorporated. Only eight of the octahedral and 16 of the tetrahedral sites are filled with metal cations. The magnetic interactions are such that the two neighboring magnetic ions on the B-site are ferromagnetically (that is parallel) coupled, whereas the much larger coupling between the magnetic ion on the A-site and the ions on the B-sites is antiferromagnetic (antiparallel). Since, there are two ions antiparallel coupled to each magnetic ion on the A-site, a net magnetic moment still results. This gives rise to the so-called ferrimagnetism, a net magnetic moment in a magnetic material in which the dominant magnetic interaction is antiferromagnetic. This behavior can be understood on the basis of superexchange interaction between the magnetic ions as explained by Anderson (1963) and Goodenough (1963).

As shown in Fig. 1 the magnetic ions in ferrites are separated by oxygen ions, which precludes a direct exchange interaction between the magnetic ions. Since, in addition, ferrites are insulators (or very poor semiconductors) exchange interaction by itinerant electrons is also not possible. The explanation for magnetism in these oxides is that the exchange interaction between the magnetic ions is mediated by the intermediate oxygen ion through superexchange (Anderson, 1963; Goodenough, 1963). Assuming that the magnetic ions M_1 and M_2 lie on a straight line through the intermediate oxygen ion O, the magnetic superexchange interaction can be explained in the following covalent bonding picture for magnetic ions with at least a half-filled shell: one of the electrons of the oxygen p-orbital directed to the magnetic ions will be excited or transferred to the ion M_1 .

On M_1 the electron can only enter an empty orbital with its spin direction antiparallel to the magnetic moment of M_1 . The other electron of the p-orbital pointing along the $M_1\text{--O--}M_2$ bond can only be excited to the M_2 ion and lower the total energy of the system, if the magnetic moment of M_2 is oriented antiparallel to M_1 . This is so because both electrons involved originate from the same oxygen p-orbital, and thus their spins must be antiparallel according to the Pauli exclusion principle. Hence, the magnetic (spin) moments of both ions should be aligned antiparallel to obtain the lowest energy state and to fulfill the Pauli principle at the same time. More about the superexchange interaction can be found in the reviews by Anderson (1963) and Goodenough (1963). For the superexchange interaction it can be derived that it is strong and antiferromagnetic along a 180° bond, i.e., when $M_1\text{--O--}M_2$ form a straight line, while it is weak and ferromagnetic along a 90° bond. This explains that the

Fig. 1 The spinel lattice structure.

Fig. 2 A typical hysteresis loop giving the response of a magnetic material to an external field, H , as changes in induction $B = M + \mu_0 H$. At high fields the B - H loop asymptotically approaches the limit B_s due to the saturation of the magnetization at M_s , the saturation magnetization. The coercive field, H_c and the initial permeability μ_i have been indicated.

interaction between the magnetic ions on the A- and B-sites in spinel ferrites, which make an angle of around 125° (see Fig. 1), is much stronger than between those on the B-sites which make an angle of around 90° (Smit and Wijn, 1959). Thus, in ferrites the dominant magnetic interaction is the AB interaction, which is typically 15–20 times stronger than the BB interaction. This causes the magnetic moments on the A and B-sites to be antiparallel oriented whereas those on the B-sites are parallel to each other.

The net magnetic moment of spinel ferrites is thus determined by the sum of the magnetic moments of the two spins on the B-site minus the moment of the A-site. This results in typical a saturation magnetization, M_s , of spinel ferrites between 143 and 560 kA m^{-1} at 0K and 120 – 477 kA m^{-1} at room temperature (Smit and Wijn, 1959), which are lower than what can be attained in metallic magnetic materials (where the dominant magnetic interaction is ferromagnetic). Fig. 2 shows a typical magnetic hysteresis loop, which gives the response of a magnetic material to an externally applied magnetic field, H . In Fig. 2 the key parameters defining a magnetic material such as the coercivity H_c and initial permeability μ_i have been indicated. Most of the spinel ferrites, with the exception of ZnFe_2O_4 , have a Curie temperature T_c in excess of room temperature, with typical values ranging from 300°C for MnFe_2O_4 to 670°C for $\text{Li}_{0.5}\text{Fe}_{2.5}\text{O}_4$ (Smit and Wijn, 1959). This T_c of ferrites is acceptable for most applications that require typically an operating temperature of the ferrite of 80°C . In most commercial applications either MnZn-ferrites or NiZn-ferrites are used. The MnZn-ferrites have the advantage that high values of the permeability μ can be reached, whereas NiZn-ferrites offer advantageously higher values of the resistivity $\rho \approx 10^5 \Omega\text{m}$ versus $1 \Omega\text{m}$ for MnZn-ferrites. This makes NiZn-ferrites more suited for high frequency application, in particular for frequencies $\geq 1 \text{ MHz}$. For applications which require a high resistivity and low material costs, MgZn-ferrites ($\rho \approx 10^6 \Omega\text{m}$) are used. For instance, the yoke-rings in the deflection unit of cathode-ray tubes were made of MgZn-ferrites as this made it possible to wind the deflection coil directly on the ferrite yoke.

For applications the magnetic softness, characterized by the permeability $\mu = dB/dH$, is relevant as it gives the response of a ferrite to an applied magnetic field H (see Fig. 2). Depending on intrinsic properties (composition, additions) and extrinsic properties (microstructure, porosity, preparation) permeabilities of $\geq 15,000$ can be obtained. The highest permeabilities are typically reached in MnZn-ferrites with large grains, which are free from pores. NiZn-ferrites generally have lower permeabilities, in commercial applications between 100 and 1000. This is because compensation of the magneto-crystalline anisotropy, as can be done in MnZn-ferrites, is not possible in NiZn-ferrites (Smit and Wijn, 1959).

The only commercial application in which monocrystalline spinel ferrites were used on a large scale was the magnetic recording head production for videocassette recorders, VCRs. For most applications ferrites are made by ceramic processing which results in polycrystalline materials. Ceramic processing is done by mixing and calcining of oxide and carbonate powders of the constituent metals. Subsequently, the powder is pressed in the desired shape and the final processing step is a sintering process following a selected temperature profile under a carefully controlled atmosphere. Typically, the sintering temperatures needed to have the required solid state reactions proceed are 1100°C or more. Details can be found elsewhere (Smit and Wijn, 1959; Snelling, 1988).

For further information about soft ferrites the reader is referred to the book by Smit and Wijn (1959) and the review by Brabers (1995) while the book by Cox (1992) provides useful background information on the theory of their electronic properties.

Applications

Traditionally, the main application areas of soft ferrites are transformer cores, inductors, and yoke-rings in cathode-ray tubes (Snelling, 1988). Since the 1990s new applications have arisen, such as cores for induction lighting and magnetic antennas for pagers. The trend in all these applications and the driving force for ferrite development is that the operating frequency increases to achieve miniaturization. This trend is illustrated in Fig. 3 which gives the weight and operating frequency of a 100 W power supply since the 1960s. A reduction in weight from approximately 8 kg to around 100 g has been achieved. The reason that

Fig. 3 The miniaturization trend in the weight of transformer cores since the 1960s. The resulting operating frequencies are indicated. The inset shows various sizes of E-cores used for transformers.

miniaturization necessitates higher operating frequencies can be understood by considering the throughput power P_{thr} of a transformer core, which can be given as:

$$P_{thr} = I_{in} \times V_{in} \quad (1)$$

with I_{in} the input current and V_{in} the input voltage. Expressing V_{in} in terms of the change of flux in time $d\Phi/dt$ gives:

$$P_{thr} = I_{in} \times Nd\Phi/dt = I_{in} \times N 2\pi f BA \quad (2)$$

with N the number of turns of the primary winding of the transformer, f the operating frequency, B the induction level in the core, and A the cross-sectional area of the core. Since the maximum induction level within the core is limited by the saturation magnetization of the ferrite, M_s , it is obvious from Eq. (2) that in order to decrease the size and hence cross-sectional area of the transformer, without sacrificing throughput power, the operating frequency f should be increased. Hence, a key aspect of modern research and development in soft ferrites is to reduce the dissipation, i.e., losses in ferrites at increasing frequencies, in the range of 100 kHz to 3 MHz.

Traditionally, three contributions to the dissipation or loss, P_{tot} , in soft ferrites are distinguished: d.c. hysteresis loss, P_h ; eddy current loss, P_e ; and residual loss, P_r . The justification for this subdivision resides in part in the differences in frequency response of each contribution, although it is to a large part phenomenological. The d.c. hysteresis loss corresponds to the dissipation incurred by cycling the d.c. B–H loop of a soft-magnetic ferrite. Through the number of times the loop is cycled per unit time, P_h depends on frequency f as $P_h = f \oint B dH$. The standard approach to limit the hysteresis loss in ferrites (Smit and Wijn, 1959; Snelling, 1988) is to facilitate domain wall movement by using ferrites with a low coercivity, H_c . This is done by selecting ferrite compositions which have a low magneto-crystalline anisotropy constant K . Ideally the ferrite should have its anisotropy compensation point, at which K passes through zero, at the required operating temperature. Typically, this is 80°C. In addition, the ferrite composition used should have a low magnetostriction constant and internal and external stress should be avoided to limit adverse magnetostriction effects. Finally, ferrites with a large grain size are used as H_c proportional to D^{-1} , with D the grain size (see van der Zaag, 1999).

The eddy current contribution is the dissipation caused by eddy currents in the ferrite. Although, due to their oxidic character, ferrites have a much higher resistivity than metallic soft-magnetic materials, their conductivity is not zero and eddy currents can occur. One can derive that the dissipation P_e is (Snelling, 1988):

$$P_e = C_e f^2 B^2 / \rho \quad (3)$$

with C_e a dimensional constant and ρ the resistivity at the measurement frequency. Hence, the P_e contribution can be separated by plotting P_{tot}/f versus f , as has been done in Fig. 4. Traditionally, the remainder of the dissipation, such as the dissipation due to ferromagnetic resonance (Snoek, 1948) has been treated as the residual loss contribution, P_r . The residual loss is thus the extra loss under a.c. measurement conditions not attributable to eddy current loss (i.e., not matching Eq. (3)). Thus, P_r has a higher than quadratic dependence on the frequency f . As Fig. 4 illustrates, at higher frequencies, both the eddy current and residual loss dominate the ferrite dissipation. Consequently, considerable work was done in the 1990s to determine and minimize the mechanisms responsible for these losses (van der Zaag, 1999).

To reduce the eddy current loss, the resistivity of ferrites should be increased. The resistivity of the ferrites used in commercial applications is determined by the resistivity of the grain boundary in these polycrystalline materials. Hence, substantial effort has been devoted to increase the grain boundary resistance by careful control of the processing conditions and by adding dopants such as Nb_2O_5 , ZrO_2 , and Ta_2O_5 besides the well-known glass-forming additions CaO and SiO_2 (Snelling, 1988). The glass formers segregate to the grain boundary to form a secondary phase, which forms an insulating layer around each grain preventing current flow from one grain to the next. At higher frequencies, also the capacitive shunting of the grain boundary impedance becomes an issue. It is thought that the addition of dopants such as Nb_2O_5 , ZrO_2 , and Ta_2O_5 play a role in reducing this effect.

The residual loss has been shown to be a dominant contribution to the dissipation of ferrites in the 500 kHz to 3 MHz frequency range. Microscopic mechanisms contributing to the residual loss are: the ferromagnetic resonance loss (Snoek, 1948)

Fig. 4 Schematic diagram of the total dissipation, P_{tot} , versus the frequency, f , for soft-magnetic ferrites. The various contributing terms to the ferrite dissipation: hysteresis loss P_h , eddy current loss P_e and residual loss P_r are indicated. All terms have been scaled by the frequency.

and the intragranular domain wall loss (van der Zaag, 1999). The former is caused by excitation of the uniform spin precession in the ferrite. For this phenomenon the well-known Snoek's law applies that (Snoek, 1948):

$$(\mu_i - 1) \times f_r = \text{constant} = g/3 \pi M_s \quad (4)$$

with f_r the ferromagnetic resonance frequency and g the gyromagnetic ratio. The latter is due to domain wall movement of intragranular domain walls within the grains of a polycrystalline ferrite (van der Zaag, 1999). Both contributions can be eliminated by using a fine-grained ferrite material. In the case of the ferromagnetic resonance loss, this causes a reduction in the permeability of the ferrite and hence an upward shift of the ferromagnetic resonance (Snoek, 1948). In well-developed ferrites the ferromagnetic resonance should be above the frequency at which the ferrite is operated. The intragranular domain wall loss is eliminated by using fine-grained ferrites in which all the grains are monodomain, i.e., intragranular domain walls are absent. Such a situation occurs in fine-grained ferrites, since below a certain grain size the monodomain state has a lower magnetostatic energy than a domain state in which a magnetic domain wall is present (van der Zaag, 1999). For further reading on the subject of dissipation in ferrites the reader is referred to (Snoek, 1948; van der Zaag, 1999).

New Developments

Ferrite Films

A new development in the field of soft-ferrite research and their application is their deposition and use in thin films (see Brabers, 1995; Suzuki, 2001). Spurred by the work on high- T_c superconductors, there has been considerable improvement in the deposition of thin film oxides, making it possible to deposit thin film ferrites in the nanometer to micrometer thickness range. The interest in these thin film ferrites is driven in part by the possibility to improve integrated inductors (Suzuki *et al.*, 1996).

In the IC industry a problem is that present inductors, amongst others for RF-applications, with typical diameters of 0.2–0.8 mm are huge in comparison to the active elements on ICs. Thus, they require a too large surface area to make integration on chip economically attractive. A possible solution would be to apply a magnetic substrate or a thin magnetic film on the coil as this may result in a reduction to a $1/4$ of the area needed for the same inductance while maintaining the quality factor Q (as is illustrated in Fig. 5 by using a ferrite substrate). In view of their resistivity, which makes application at higher frequencies possible, ferrite films deposited on the integrated inductors can provide a possible solution. A problem is the high substrate temperature ($=600^\circ\text{C}$) needed to assure the formation of a ferrite film with a proper cation distribution and an adequate grain size to assure that the ferrite films have a sufficiently high permeability. Wet-chemically prepared films grown by ferrite plating at 80°C provide a useful method as permeabilities ≥ 25 have been obtained in μm thick MnZn-ferrite films in the frequency range up to 10 MHz (van der Zaag *et al.*, 1999). For approximately $0.7 \mu\text{m}$ thick NiZn-ferrite plated films permeabilities of around 80 in the 100 MHz–1 GHz range have been obtained (Obi *et al.*, 2011).

For higher frequencies in the microwave, GHz regime, the μ of MnZn-ferrite and NiZn-ferrites are too low and yttrium iron garnets (YIG) are the materials of choice. The advances made, using these YIG magnetic oxides films for microwave devices such as isolators, circulators and phase shifters has been reviewed by Harris (2011).

Another interesting trend is the work on magnetite, Fe_3O_4 , ultrathin films in view of their intrinsic fully spin-polarized electron transport for magnetoresistive sensors (Coey *et al.*, 1998; Seneor *et al.*, 1999). Fe_3O_4 is a half-metallic ferromagnet as it has a gap in the minority spin band, whereas there is no gap in the majority spin band (Brabers, 1995). Thus, for the majority spins Fe_3O_4 behaves as a metal with spin-polarized electron transport along the B-sites by hopping conduction. This property is of interest as it could be employed in magnetic tunnel junctions leading to a magnetic field sensor element with, theoretically, an infinite tunnel

Fig. 5 The quality factor, $Q = \omega L/R$ with ω the angular frequency, L the inductance and R the resistance of the inductor, of two planar inductors, one on a glass substrate and the other on a NiZn-ferrite substrate. Although both inductors have comparable inductances ($L = 33$ and 28.4 nH) and Q , the inductor using a ferrite substrate has half the diameter, i.e., needs $1/4$ of the area.

Fig. 6 (a) Anti-phase domains form when layer of a spinel, such as magnetite (Fe_3O_4), grows epitaxially on a rock salt substrate such as MgO . The domains shown are related to a reference domain by in-plane and out-of-plane shift vectors. An example of each type is shown in the drawing. A characteristic of the out-of-plane shifted domains is that the rows of octahedrally coordinated cations in atomic layers on the same level are oriented perpendicular to each other. (b) Example of antiphase boundaries (APBs) seen by transmission electron microscopy (TEM) for a 200 nm Fe_3O_4 layer grown by molecular beam epitaxy (MBE) on MgO (001). Only APBs with out-of-plane shift vectors are visible in the TEM picture. Reproduced from Hibma, T., Voogt, F.C., Niessen, L., *et al.*, 1999. Anti-phase domains and magnetism in epitaxial magnetite layers. *J. Appl. Phys.*, 85. 5291–5293, with the permission of AIP Publishing.

magneto-resistance (TMR) effect, as electrons with minority spin cannot pass the Fe_3O_4 layer. The degree to which a proper Fe_3O_4 layer can be grown in these magnetic tunnel junctions, or needs to be grown to have a positive effect on the magneto-resistance is not known precisely. The same holds for the role played by the interfaces of the Fe_3O_4 layer or antiphase boundaries (APBs). APBs arise because Fe_3O_4 has a lower symmetry and a larger unit cell, see Fig. 1, than the substrates typically used in epitaxial growth (MgO , NiO , CoO) which have a rock salt structure (Margulies *et al.*, 1997; Hibma *et al.*, 1999). Fe_3O_4 can nucleate on such a substrate in 8 unique ways, see Fig. 6(A). These different islands are not able to match up to form a continuous Fe_3O_4 layer without stacking faults, see Fig. 6(B) (Hibma *et al.*, 1999). The resulting Fe_3O_4 layer will have a continuous O_2 -sublattice, concomitant with a fragmented, discontinuous cation sublattice, giving rise to APBs.

The role of APBs in relation to the observed reduced magnetization of Fe_3O_4 thin films compared to the saturation magnetization of bulk Fe_3O_4 (Margulies *et al.*, 1997) or whether so-called “dead” magnetic interface layers caused this (van der Heijden *et al.*, 1996) has been the subject of considerable debate. The study by Chang *et al.* (2016) into the epitaxial growth of Fe_3O_4 and its interface structure has managed to elucidate this. These authors have studied the growth of ultrathin Fe_3O_4 films grown by molecular beam epitaxy (MBE) through soft X-ray absorption spectroscopy (XAS). From this experiment the following picture emerges, see Fig. 7: When depositing Fe_3O_4 , first basically a charge neutral rock salt FeO layer with 25% Fe vacancies is formed. This is a charge neutral or nonpolar layer. When depositing the second monolayer, first again such a nonpolar layer similar to the first layer is formed. However, now both monolayers can provide each the Fe^{3+} ions needed to generate the A-site Fe^{3+} ions. Since this layer is sandwiched between two layers from which the Fe^{3+} ions originate, charge neutrality is maintained. The same mechanism operates when the third monolayer is deposited. The elegant nature of this model for the growth process of Fe_3O_4 on

Fig. 7 Model for the growth process of polar Fe_3O_4 (001) thin films: (a) One monolayer, (b) Two monolayer and (c) Three monolayers. Reproduced from Chang, C.F., Hu, Z., Klein, S., *et al.*, 2016. Dynamic atomic reconstruction: How Fe_3O_4 thin films evade polar catastrophe for epitaxy. *Phys. Rev. X* 6, 1–7. (0401011). doi:10.1103/PhysRevX.6.041011.

rock salt substrates, such as MgO (001), is that it explains the experimental observation of the authors that Fe_3O_4 films below 6 monolayer thick lack Fe^{3+} ions compared to bulk Fe_3O_4 . Moreover, this model deals with the polar catastrophe, which would occur if one considers a simple layer-by-layer deposition of the Fe_3O_4 spinel structure (Chang *et al.*, 2016). The authors thus suggest that the Fe^{3+} ions move within the films during the deposition process to give rise to the A-site. This model for the Fe_3O_4 growth on MgO (001) seems to support the proposition of a “dead” layer model at Fe_3O_4 - MgO interface as the low amount of A-site present at the interface may lead to missing superexchange interaction at the interface which may lead to a magnetically “dead” interface. Rather than the APB approach, in which such behavior would be the consequence of superparamagnetic behavior of the antiphase domains (Voogt *et al.*, 1998).

This understanding of the growth process and interface structure of Fe_3O_4 on an epitaxial substrate may also be relevant to guide the application of ferrite layers in magnetic devices.

A first indication of an increased magneto-resistance effect due to the incorporation of Fe_3O_4 layers in magnetic tunnel junctions was reported by Seneor *et al.* (1999) and van der Zaag *et al.* (2000). More recent work has highlighted the importance of structural improvements such as the reduction of the antiphase boundary density, by using a Fe-underlayer in $\text{Fe}_3\text{O}_4/60 \text{ \AA}$ $\text{MgO}/\text{CoFe}/\text{IrMn}/\text{Ta}$ tunnel junctions grown on Al_2O_3 (0001). Importantly, this work showed that as the tunnel junctions improved, as measured by a large resistance-area product, the TMR ratio became larger and more negative, as expected for an intrinsic TMR effect. In the best tunnel junctions a TMR ratio of -26% was obtained at room temperature (Kado, 2008).

In addition, ferrite layers (XFe_2O_4 with $\text{X} = \text{Co}, \text{Ni}$ or Mn) have been studied as spin filters to cause spin polarized current in a detection layer, see the review by Moussey (2013). The problem encountered so far is that the very thin (3 nm) XFe_2O_4 spin filters suffer from thermally activated transport due to the presence of defects. Also for spin current generation for spintronic applications, magnetic insulators are of interest as these materials can generate and transmit pure spin currents with minimal dissipation from eddy currents. Thus far, most studies have applied YIG for this purpose. However, also spinel ferrite layers, such as $(\text{NiZn})_1(\text{AlFe})_2\text{O}_4$ and $\text{Mg}(\text{AlFe})_2\text{O}_4$ films, have been studied for this purpose. These films exhibit good spin pumping properties, have the advantage that they can be grown on various substrates, and have significant in-plane anisotropy, leading to high spin-wave frequencies (see, for instance, Riddiford *et al.*, 2019).

Life Sciences Applications: Magnetic Beads

Another interesting new application is the use of so-called magnetic beads in the life sciences and in *in vitro* diagnostics (Pankhurst *et al.*, 2009; Gijs *et al.*, 2010; Pamme, 2012; van Reenen *et al.*, 2014). These beads are composed of small ($< 20 \text{ nm}$) Fe_3O_4 or maghemite, $\gamma\text{-Fe}_2\text{O}_3$, nanoparticles embedded in a polymer matrix, see Fig. 8 for an example. These nanoparticles are so small that their thermal energy exceeds their magnetostatic energy at room temperature. This gives rise to superparamagnetic behavior, i.e., the beads will only exhibit magnetic behavior in an applied magnetic field. In applications, this has the advantage that bead agglomeration will only occur in an applied magnetic field. Upon removal of the field the beads will redisperse.

These beads can be functionalized by conjugation of biomolecules (such as antibodies or oligonucleotides) to the surface so that they can bind selectively specific antigens or nucleic acids fragments in a sample. Such beads have found application in *in vitro*

Fig. 8 Scanning electron microscope image of a magnetic bead composed of Fe_3O_4 nanoparticles embedded in a polymer matrix used in the life sciences and *in vitro* diagnostics.

diagnostics to influence or speed-up assay time through magnetic actuation (Gijs *et al.*, 2010; Pamme, 2012; Moerland *et al.*, 2019). Magnetic beads also have found application in nucleic acids purification and collection under suitable buffer conditions, when they are either silica or carboxyl coated (Hawkins *et al.*, 1994) or both.

Finally, ferrite nanoparticles are also finding use in *in vivo* applications as contrast agent in MRI and magnetic particle imaging and as agents to deliver hyperthermal treatment of tumors, where local heating is used to treat a tumor (Pankhurst *et al.*, 2009).

Introduction

The intrinsic coupling of electricity and magnetism, which goes back to Michael Faraday and was unified by Maxwell equations, plays essential roles in modern physics. Among them, the coupling interaction in multiferroic materials has drawn great interest due to their promising applications in recent times. Multiferroics are defined as materials that exhibit two or more of the primary ferroic properties: ferromagnetism, ferroelectricity, ferroelasticity in the same phase (Schmid, 1994). Nowadays, the non-primary orders such as antiferromagnetism and composites of individual ferroics are also included in the multiferroics, which is more often used to refer specifically to magnetoelectric (ME) coupling (Fiebig, 2005). The ME response is the control of electric polarization by applying a magnetic field (direct ME effect) or manipulation of magnetization by applying an electric field (converse ME effect) (Nan *et al.*, 2008). These materials are extremely interesting due to their physics that one can modify the magnetic state by changing electric field, which is favored by many practical applications. There are already very good reviews of this field (Fiebig, 2005; Spaldin and Fiebig, 2005; Cheong and Mostovoy, 2007; Khomskii, 2006; Eerenstein *et al.*, 2006; Wang *et al.*, 2009; Khomskii, 2009; Nan *et al.*, 2008; Srinivasan, 2010; Wang, 2016; Tu *et al.*, 2019), here, we will cover the most emphasis of them and of course with substantial additions.

The birth of the ME effect that crystals could exhibit simultaneously more than one ferroic order probably originated with Curie (1894) in the 19th century. Debye (1926) coined the term “magnetoelectric” a few years after the first unsuccessful attempts to demonstrate the ME effect experimentally. Before the first demonstration of intrinsic ME behavior in a single-phase compound, Tellegen (1948) proposed the idea of synthesizing a composite material that exhibited a ME effect. But the real considerable investigations in this field began in 1960s after several papers were given by Landau *et al.* (2013), Dzyaloshinskii (1960) and Astrov (1960), who theoretically predicted and experimentally observed the linear ME effect of the well-known antiferromagnet Cr_2O_3 . The interest in multiferroics faded somewhat after extensive activities in 1960s and 1970s, however, the renaissance of ME multiferroics appeared in 2000s (Spaldin and Fiebig, 2005). According to the microscopic sources of ferroelectricity, multiferroics are normally divided into two groups: type-I and type-II (Khomskii, 2009). There are several different origins of ferroelectricity: lone pairs, charge ordering, etc. while the microscopic source of magnetism is mostly same: the exchange interactions between the localized electrons that lead to an equivalent localized spin, or magnetic moment. Due to the different microscopic origins of ferroelectricity and ferromagnetism in type-I multiferroics, they are independent of each other although there is a poor coupling between them. The coupling is very strong in type-II multiferroics, in which ferroelectricity is in fact caused by a type of magnetic ordering. The resurgence of the entire field of multiferroics is owing to the discovery of type-II multiferroics (Kimura *et al.*, 2003; Hur *et al.*, 2004), though they are less promising for practical applications due to the much smaller polarization in these materials. This situation also facilitates the investigations on composite multiferroics consisting of ferroelectrics and magnets in the form of multilayers and self-organized nano-structures (Ramesh and Spaldin, 2007). Recent developments in thin film growth techniques and experimental methods for observing magnetic and electric domains, together with theoretical breakthroughs in understanding ME coupling, have generated a great deal of studies on magnetoelectric multiferroics (Fiebig, 2005; Spaldin and Fiebig, 2005). However, none of the existing single-phase multiferroics materials are attractive for applications in the short term, because they are not able to combine both large and robust magnetic and electrical ordering at room temperature. By establishing two-phase composite multiferroics that consist of a ferromagnetic constituent (such as FeGaC (Liang *et al.*, 2018b; Dong *et al.*, 2018) and FeCoC (Wang *et al.*, 2019)) and a ferroelectric constituent [such as $\text{PbZr}_{1-x}\text{Ti}_x\text{O}_3$ (PZT)], this dilemma can be circumvented. The interaction of the elastic components between the magnetostrictive and piezoelectric constituents is the origin of magnetoelectric effects in such composites. Therefore, the emphasis of this chapter will be multiferroic or magnetoelectric composites.

Multiferroic materials play a key role in achieving strong ME coupling in multiferroic heterostructures, which has been of paramount importance for achieving multiferroic devices with large tunability. The strength of ME coupling can be represented by the two ME coupling coefficients: direct ME coupling coefficient $\alpha_{\text{direct}} = dP/dH$, and converse ME coupling coefficient $\alpha_{\text{converse}} = dM/dE$. We can obtain the contributions to the ME effect from the expansion of the free energy:

$$-F(\vec{E}, \vec{H}) = \frac{1}{2} \epsilon_0 \epsilon_{ij} E_i E_j + \frac{1}{2} \mu_0 \mu_{ij} H_i H_j + \alpha_{ij} E_i H_j + \frac{\beta_{ijk}}{2} E_i H_j H_k + \frac{\gamma_{ijk}}{2} H_i E_j E_k + \dots, \quad (1)$$

where $\vec{E}$ and $\vec{H}$ are the electric and magnetic field, respectively. $\hat{\epsilon}$ and $\hat{\mu}$ are the electric and magnetic susceptibilities. The tensor $\hat{\alpha}$, which corresponds to the induction of polarization by a magnetic field or of magnetization by an electric field, describes linear magnetoelectric coupling, while the third-rank tensors $\hat{\beta}$ and $\hat{\gamma}$ represent higher-order ME coefficients. The prefix “linear” is

generally omitted and simply referred as the “ME effect”. By differentiating F with respect to E_i , H_i , and then setting H_i , $E_i = 0$, we can easily establish ME effect in the form of $P_i(H_j)$ or $M_i(E_j)$:

$$P_i = \alpha_{ij}H_j + \frac{\beta_{ijk}}{2}H_jH_k + \dots, \quad (2)$$

$$\mu_0 M_i = \alpha_{ji}E_j + \frac{\gamma_{ijk}}{2}E_jE_k + \dots, \quad (3)$$

For the composite materials, not only the properties of the constituents but also the interaction between them can influence the properties of the composite materials that consist of two or more single-phase compounds. Three classes of effects can be distinguished (Ryu *et al.*, 2002): sum, scaling, and product properties. Therefore, the ME effect is conveniently accomplished by combining magnetostrictive and piezoelectric compounds. The ME coefficient of this type of composite can be established in a crude way as (Nan, 1994):

$$\alpha_{ME} = \frac{dE}{dH} = \frac{dS}{dH} \times k_c \times \frac{dE}{dS}, \quad (4)$$

where $\frac{dS}{dH}$, $\frac{dE}{dS}$ represent magnetostrictive and piezoelectric coefficients, respectively. k_c is denoted as the coupling coefficient between magnetostrictive and piezoelectric single-phase materials.

As for multiferroic composite architectures, there are three common structures that create strong enough coupling between them for multifunctional applications (Spaldin and Ramesh, 2019). Fig. 1(a) shows a classic ME composite consisting of ferromagnetic LuFe_2O_4 and ferroelectric LuFeO_3 multilayers developed by thin film growth techniques. Instead of horizontal layered system, a vertically mediated architecture with three-dimensional ferro- or ferrimagnetic nano-pillars embedded in a ferroelectric phase. The third structure as shown in Fig. 1(c), is the strain-induced mixed phase of particulate nano-composites.

Magnetoelectric Compositions in Composites

The multifunctional properties of multiferroic composites facilitate the development of novel electronic devices for various sensing, transduction, and antenna applications. There are several advantages for composite architectures, such as large remnant magnetizations and polarizations, as well as strong enough coupling, which allow them to be used in applications. Due to the large ME coupling coefficients, easy of fabrication and design flexibility, ME composites have been extensively studied in recent years. Different interaction structures, fabrication methods and materials of ME composites are taken into account here for developing high performance composites with strong ME coupling.

The interfacial connectivity and bonding of the piezoelectric and magnetostrictive phases have a huge influence on the strain-mediated ME coupling in the composites. The mechanical coupling coefficient k_c , which facilitates efficient strain transfer, can be used to characterize mechanical bonding between different phases. The two-phase ME composites have been generally classified as 0–3, 1–3, and 2–2 connectivity, as shown in Fig. 1, although various schemes have been proposed for designing ME composites (Palneedi *et al.*, 2016; Spaldin and Ramesh, 2019). The number here represents the dimension of the magnetostrictive and piezoelectric phases, respectively. For example, 0–3 composites are composed of magnetostrictive particles and piezoelectric matrix. In the 1–3 composites, magnetostrictive fibers/rods/tubes/wires are embed in the piezoelectric matrix. 2–2 composites consist of alternating magnetostrictive and piezoelectric laminate phases, which can be different shapes and dimensions. A variety of parameters and variables, such as geometries, layer structures and volume fraction can be altered to tailor the properties of the ME composites. The 2–2 composites are more often utilized for applications because of their simplicity of fabrication and unchanged physical characteristics of individual phases. The 2–2 composite structure, which has inherent advantages in terms of fabrication process and physical characteristics, has been confirmed from both theoretical and experimental results that it presents higher ME interactions compared to 0–3 and 1–3 structures.

Ceramic sintering, hot pressing, and spark plasma sintering (SPS) are some typical methods for synthesizing of 0–3 composites (Islam *et al.*, 2008a,b; Srinivasan *et al.*, 2004; Jiang *et al.*, 2007). By selecting individual phases, their sizes and other parameters, we can easily design the properties of 0–3 composites. However, the experimental ME response of 0–3 composites is much lower than that of theoretically calculated ones. This can be attributed to different reasons: the interdiffusion and misfit strain between the piezoelectric and magnetostrictive phases, and current leakage of the composites. Several methods such as a controlled annealing (Islam and Priya, 2006) and an insulating PZT layer (Islam *et al.*, 2008a,b) were employed to solve these problems. Readers can refer to Palneedi *et al.* (2016) for fabrication of the 1–3 type bulk ME composites since very few attempts have been made to this kind of composites. Epoxy bonding and co-firing (Ryu *et al.*, 2002; Dong *et al.*, 2006) are two most common ways for preparing bulk 2–2 laminate composites. Bilayer and sandwich structures, in which piezoelectric layer is sandwiched by two magnetostrictive layers, are usually used to prepare the 2–2 samples. The epoxy layer, for example silver epoxy, is required to be as thin as possible to acquire high performance ME composites although the mechanically soft epoxy layer can suppress the interface ME coupling. Co-firing process provides advantages of both cost-effective mass production and the interface strengthening, however, the high temperature process that is similar to 0–3 composites sintering is still detrimental to the good ME coupling. As miniaturization and multifunctionality of devices become more popular, thin film ME composites are highly desired for integrated ME devices. Improved ME coupling can be achieved in film-based composites because of the direct bonding of individual phases. Furthermore,

Fig. 1 Multiferroic composite architectures. (a) In classic horizontal composites, a ferroelectric material is layered with a ferro- or ferrimagnet. (b) A vertically aligned nanocomposite of a ferro/ferrimagnet embedded epitaxially in a ferroelectric phase in which coupling is mediated through three-dimensional coherent heteroepitaxy. (c) Schematics of a nanocomposite of BiFeO_3 (BFO) formed at the strain-induced morphotropic phase boundary. Reproduced from Spaldin, N., Ramesh, R., 2019. Advances in magnetoelectric multiferroics. *Nature Materials* 18 (3), 203–212.

smaller electric voltage is required for thin films than bulk samples because large electric fields can be applied to thin films. The advanced thin film deposition techniques, flexibility in the property designs, as well as interfacial strain engineering gives rise to studies on film-based ME composites. A variety of thin film ME composites have been prepared with excellent crystal epitaxy and coherent interfaces although the ME coefficients are very low in the reported papers due to substrate clamping effect. By dispersing magnetic nanoparticles into piezoelectric matrix with larger interfacial area, the ME coupling of 0–3 type composites can be boosted since the strain-mediated ME coupling (McDannald *et al.*, 2013). Though the 1–3 type ME composites, which exhibit a reduced substrate clamping effect as a result of large interfacial area, can be prepared via self-assembly process at the micro- and

nanoscale, it remains challenging to apply them in practical applications due to the difficulty on designing samples of such structures (Aimon *et al.*, 2015). Various deposition methods including physical vapor deposition (PVD), pulsed laser deposition (PLD), chemical vapor deposition (CVD), molecular beam epitaxy (MBE), spin coating, spin-spray techniques, etc., have been developed for preparing film-based 2–2 type ME composites (Sun and Srinivasan, 2012). For thick film 2–2 ME composites, several techniques such as aerosol deposition, electrodeposition, and granule spray in vacuum deposition (GSV) are employed to prepare samples. Recently, laser or light radiation, which is commonly used in printed electronics, is used to induce localized annealing effect for controlling the thermal diffusion in the nanostructured films.

The selection of appropriate piezoelectric and magnetostrictive materials is particularly significant on getting a composite with large ME coupling. Some typical piezoelectric and magnetostrictive materials used as constituents of ME composites are listed in Table 1. Among all piezoelectric materials used for bulk ME composites, the lead-based piezoelectric PMN-PT single crystal exhibits the highest piezoelectric constant, while PZT ceramics are also widely used in ongoing works because of their very low cost. Because of the extremely high Q_m , LiNbO_3 crystal could be a desired material for low-loss ME devices. But AlN seems the most favorable choice with respect to film ME devices due to the compatibility with MEMS processes although the piezoelectric response is poor. As for the piezomagnetic phase, Terfenol-D (with a giant magnetostriction) and Metglas (with a high permeability and piezomagnetic coefficient) are widely used as high-performance magnetostrictive alloys, while Ni is a good candidate for self-biased ME device (Chu *et al.*, 2018a). With respect to thin film ME composites, the largest piezomagnetic coefficients have been found in amorphous FeGaC or FeCoSiB films.

Characterization and Modeling

The development of a variety of new experimental and theoretical methods for studying time-resolved and spatial multiferroic phenomenon is discussed in this section. With the help of scanning probe techniques including piezoforce, electron scanning, conducting atomic and magnetic force microscopes (PFM, SEM, CAFM, and MFM), scanning transmission X-ray microspectroscopy (STXM), the spatial resolution of studying the spin, charge, and orbital degrees is able to approach the unit cell dimensions (Gross *et al.*, 2017; Strocov *et al.*, 2010). For the time-resolved characterization of multiferroic phenomenon, the ultrafast synchrotron X-ray is utilized to study dynamics of multiferroic composites (Orenstein, 2012).

Given that magnetoelectric composites consist of piezoelectric and magnetostrictive phases, it is crucial to evaluate the properties of these materials. There are a variety of tools that are well-known in multiferroic areas, such as vibrating sample magnetometer (VSM) for measuring magnetization and anisotropy field, ferromagnetic resonance (FMR) for measuring linewidth and Gilbert damping constant, etc. But the most significant parameters of ME composites are the magnetostriction constant of magnetic phase and piezoelectric coefficient of ferroelectric phase due to the fact that ME coupling strength is the result of a product of the piezoelectric effect and magnetostrictive effect. Owing to the prevalence of integrated ME composites devices and difficulties on characterization of thin-film piezoelectric and magnetostrictive materials, here, we introduce several characterization techniques that have been developed for evaluating these properties. In order to acquire the piezoelectric coefficients of thin films, a variety of techniques were exploited to do the measurements (Kholkin *et al.*, 1996; Dubois and Muralt, 1999a; Dufay *et al.*, 2015; Conde and Muralt, 2008; Liu *et al.*, 2002). Based on double-beam interferometer, a direct measurement of piezoelectric coefficients can be done. However, the discrimination of the true films expansion and the bimorph-like bending of the sample should be carefully taken care of. Besides, indirect extraction of piezoelectric coefficients based on different micromechanical system (MEMS) such as cantilever structures (Dufay *et al.*, 2015), surface acoustic wave (SAW) resonators (Liu *et al.*, 2002), and bulk acoustic wave (BAW) resonators (Conde and Muralt, 2008), was also proven to be effective. The tip displacement of bending-mode PZT cantilever deposited on a 16 μm -thick aluminum substrate was measured by a laser vibrometer under controlled electric field to determine the transverse piezoelectric coefficient d_{31} . A hysteresis change of both the resonance and antiresonance frequencies of thin film bulk acoustic resonator (FBAR) under applied bias was used to extract dielectric, piezoelectric, and elastic properties of the [111]-textured PZT film. The coupling factor k_t^2 of a BAW resonator can be utilized to calculate d_{33} or ε_{33} if a pure thickness mode is excited, which is same for calculating d_{31} or ε_{31} of SAW resonator. As for magnetostriction measurements, several techniques have been proposed, which can also be generally classified as either direct or indirect methods (Ekreem *et al.*, 2007). The most commonly used methods include the capacitance method based on cantilever structure (Klokholm, 1976), optical method utilizing rotating magnetic fields (Tam and Schroeder, 1989) and nano-indentation method (Shima and Fujimori, 1999). Capacitance method utilizes the tunable capacitance of the plate capacitor when thin film is on top of the cantilever, which serves as an oscillator. When a DC magnetic field is applied to the cantilever structure, a capacitance change can be induced as a consequence of deflection of the cantilever, which leads to the shift in resonant frequency of the oscillator, and therefore the magnetostriction can be derived. In optical approach, a rotating magnetic field is exploited to provide high-accuracy and non-contact measurements of the samples despite of the complex optical system. Nano-indentation method based on a commercial system is able to characterize both elastic properties and magnetostriction of thin films on top of cantilevered substrates.

By using a non-contact optical technique, Dong *et al.* (2018) recently developed a simple, compact, and sensitive system including both magnetostriction tester and delta-E tester to measure magnetostriction, piezomagnetic coefficient, and delta-E effect. The schematic of the proposed magnetostriction tester is shown in Fig. 2(a). A rotating adjustable AC magnetic field with a maximum value of 300 Oe is generated by two pairs of mutually perpendicular set Helmholtz coils with equivalent amplitude and 90° phase shift current. Similar as the cantilever method for measuring piezoelectric coefficients, the tip displacement of the

Table 1 Parameters of typical piezoelectric and piezomagnetic materials

Parameters	Piezoelectric phase					Piezomagnetic phase

cantilever is detected by a MTI-2000 fiber-optic sensor due to the strain change in the magnetostriction film. **Fig. 2(b)** shows the schematic of the proposed delta-E tester, which is very similar to the magnetostriction tester. Second vibration mode of the cantilever is excited by applying a 0.1 Oe AC driving field through a solenoid with the frequency swept around 1555 Hz. A DC bias magnetic field is generated by the Helmholtz coil to induce magnetic domain change in the magnetostrictive films, and thus

resulting in the change of Young's modulus. According to the modified Ruler-Bernoulli beam theorem, the change of Young's modulus can be derived by measuring the shift in resonant frequency of the cantilever. Some typical magnetostrictive films such as Ni, Co, FeGa, etc. with well-known magnetostriction values are used to calibrate the system. Fig. 2(c) shows the measured magnetostriction of some magnetostrictive thin films after system calibration and Fig. 2(d) shows the measured magnetostriction and piezomagnetic coefficient for as-deposited and annealed FeGaB thin films. The change in Young's modulus of FeGaB thin film is also measured and shown in Fig. 2(e) by using delta-E tester and Fig. 2(f) shows the derivative of Young's modulus as regard with the magnetic field (dE/dH).

For single phase multiferroic materials, first-principles (Zhong *et al.*, 1994) density functional theory (DFT) has been the standard method for modeling the behaviors of insulating magnetically ordered materials such as multiferroics, while second-principles (García-Fernández *et al.*, 2016) calculations are becoming a promising method for understanding larger systems – for example, heterostructures, domain walls, and defects (Karpinsky *et al.*, 2017). For layered multiferroic composites, a model for ME coupling in a bilayer of magnetostrictive and piezoelectric phases was proposed by Harshe *et al.* (1993) and Avellaneda and Harshé (1994) in their innovative works. Several theoretical models have been presented recently and applied to various systems, including ferrites, metals, and alloys for magnetostrictive phase and lead zirconate titanate (PZT), lead magnesium niobate-lead titanate (PMN-PT), and polyvinylidene difluoride (PVDF) for the piezoelectric phase, for low-frequency ME coupling in bilayer structures (Harshe *et al.*, 1993; Avellaneda and Harshé, 1994; Bichurin *et al.*, 2003b; Liu *et al.*, 2004). The ME voltage coefficient $\alpha_{ME} = \frac{dE}{dH}$ can be estimated by solving the elastostatic and electrostatic equations. The expression for longitudinal ME voltage coefficient can be obtained in the form of

$$\alpha_{E33} = \frac{dE_3}{dH_3} = 2 \frac{\mu_0 k v (1 - \nu) d_{31}^p q_{13}^m}{\{2d_{31}^p 2(1 - \nu) + \epsilon_{33}^p [(s_{11}^p + s_{12}^p)(\nu - 1) - \nu(s_{11}^m + s_{12}^m)]\}} \times \frac{[(s_{11}^p + s_{12}^p)(\nu - 1) - k v (s_{11}^m + s_{12}^m)]}{\{[\mu_0(\nu - 1) - \mu_{33}^m v][k v (s_{12}^m + s_{11}^m) - (s_{11}^p + s_{12}^p)(\nu - 1)] + 2q_{31}^m 2k v^2\}}, \quad (5)$$

And the transverse ME voltage coefficient is given as

$$\alpha_{E31} = \frac{dE_3}{dH_1} = \frac{-k v (1 - \nu) (q_{11}^m + q_{21}^m) d_{31}^p}{\epsilon_{33}^p (s_{12}^m + s_{11}^m) k v + \epsilon_{33}^p (s_{11}^p + s_{12}^p) (1 - \nu) - 2k d_{31}^p 2(1 - \nu)}, \quad (6)$$

Here m and p indicate the magnetostrictive and piezoelectric phases, respectively; q and d are the magnetostrictive and piezoelectric coupling coefficients, respectively; s is the compliance coefficient; ϵ is permittivity at constant stress; μ is the tensor permeability; and $\nu = v^p / (v^p + v^m)$, where v^p and v^m denote the volume of the magnetostrictive and the piezoelectric layers, respectively. Due to the strain-mediated ME coupling in multiferroic composites, the strength of ME interactions would be enhanced with orders of magnitude when the AC magnetic field is applied at frequencies corresponding to resonant modes in the ME composites, for example, electromechanical resonance (EMR) (Bichurin *et al.*, 2003a) and bending modes (Pan and Heyliger, 2003; Petrov *et al.*, 2009). The models and theories of these modes were developed in the reference mentioned above.

Applications

The interaction between the electric and magnetic phases in a multiferroic material opens up the possibility of novel devices. Wood and Austin (1974) investigated possible applications for single-phase ME materials and concluded that it was not possible for practical devices due to the weak coupling. However, multiferroic composites presented a very strong ME coupling, which have led to a great deal of applications. Here, we focus on MEMS magnetoelectric composites device applications of our group and direct readers to other reviews for bulk and other multiferroic devices. Our group has demonstrated a variety of MEMS devices based on ME composites, including magnetic-field sensors (Nan *et al.*, 2013; Chu *et al.*, 2019), tunable inductors (Gao *et al.*, 2014a,b; Chen *et al.*, 2020), band-pass and band-stop filters (Lin *et al.*, 2016; He *et al.*, 2018), and ME antennas (Nan *et al.*, 2017; Liang *et al.*, 2018a; Dong *et al.*, 2020). Regarding the bulk ME composites devices, we introduce some reviews (Nan *et al.*, 2008; Srinivasan, 2010; Spaldin and Ramesh, 2019) for consideration and some work from our group on sensors (Li *et al.*, 2017; Liang *et al.*, 2020), inductors (Lou *et al.*, 2009; Su *et al.*, 2016), isolator (Tu *et al.*, 2018), and antennas (Yang *et al.*, 2008) although no details are described here.

Magnetoelectric Sensor

It has been an open challenge in detecting weak DC and low frequencies AC magnetic fields for many years. Since the demonstration of strong ME coupling in magnetostrictive/piezoelectric ME heterostructures, exciting progress was made recently on highly sensitive magnetometers (Zhao *et al.*, 2009; Israel *et al.*, 2008). The DC magnetic field dependence of ME interaction can be utilized for DC magnetic field sensing. A self-biased ME sensor based on a 215 MHz AlN/FeGaB nano-plate resonator was demonstrated in our work. A low limit of detection for DC magnetic fields of ~ 300 pT in unshielded environment was achieved by increasing the resonance frequency of NEMS ME sensor to 215 MHz. The ME heterostructure is composed of seven Pt inter-digital electrodes on the bottom of

the AlN layer and low-loss magnetostrictive FeGaB/Al₂O₃ multilayer as the electrically floating top electrode. By diminishing substrate clamping effect, the Si substrate underneath the resonator is completely removed to achieve a strong ME coupling and high sensitivity.

The admittance curve and the Butterworth–van Dyke (BVD) model fitting of the NEMS magnetic field sensor are depicted in Fig. 3(a) showing an electromechanical resonance frequency of 215 MHz. A high quality factor of 735 and a high electro-mechanical coupling coefficient k_t^2 of 1.54% in air were extracted from the BVD model at zero bias magnetic field, which is comparable to what is typically reported in AlN nano-plate resonator (Rinaldi *et al.*, 2011). One example of the BVD equivalent electrical circuit of the resonator is shown in Fig. 3(b), in which R_s represents the resistance of metal electrodes and contact resistance, R_{op} is the parasitic resistance from substrate, C_0 denotes the device capacitance from the Pt/AlN/FeGaB stack, C_M , L_M , and R_M are the motional capacitance, inductance, and resistance, respectively. The delta-E effect, which is known as the change of Young's modulus by applying a DC bias magnetic field, results in the change in the electromechanical resonance frequency of the AlN/FeGaB heterostructure. Strong ME coupling in the NEMS ME magnetic field sensor was demonstrated in Fig. 3(c), which shows the admittance curves at various DC bias magnetic fields applied along the length direction of the resonator. As shown in Fig. 3(d), a similar trend, which first decreases and then increases with the increase of bias field, for both resonance frequency f and peak admittance amplitude Y at the resonance frequency is exhibited with DC bias magnetic field.

The resonance frequency of the magnetoelectric NEMS resonator can be expressed by

$$f_0 = \frac{1}{2W_0} \sqrt{\frac{E_{eq}}{\rho_{eq}}}, \quad (7)$$

with W_0 being the pitch of the finger electrodes forming the interdigital transducer (IDT), E_{eq} being the equivalent Young's Modulus and ρ_{eq} being the equivalent density of the resonator. By applying a DC magnetic field, a magnetostrictive strain can be induced due to the delta-E effect, and therefore a changed equivalent Young's modulus of the NEMS ME magnetic sensor. In order to measure the sensitivity of the resonator to DC magnetic fields, an extremely small magnetic field was applied to the sensor in an unshielded environment. The value of the admittance amplitude starts to scatter at 300 pT, which indicates a limit of detection

Fig. 3 (a) Admittance curve and BVD model fitting of the fabricated NEMS magnetic field sensor. (b) The BVD equivalent electrical circuit of the resonator. around 300 pT. The demonstrated RF NEMS ME magnetic sensor, which is based on the magnetic field dependence of admittance, makes it excellent self-biased magnetometer compared to conventional ME sensor that relies on the ME output voltage.

Magnetoelectric Inductor

As one of the fundamental components of electronic circuits, various inductor designs, and tuning methods have been employed in different applications. [Bedair et al. \(2012\)](#) described the design, microfabrication, and testing of integrated and continuously tuned RF copper inductors with low-power large-throw lead-zirconate-titanate (PZT) actuators. A planar solenoidal inductor, which is designed and fabricated using a two-metal MEMS process, with tunable inductance from 1 to 3.3 nH and a Q-factor of more than 20 was proposed by [Shirane et al. \(2012\)](#). A coupled inductor pair with self-inductances of 15 and 21 nH was implemented showing Q_s exceeding 40 at 800 MHz with a microfabrication technology ([Shim et al., 2012](#)). In this work, we reported novel integrated GHz magnetic inductors based on solenoid structures with FeGaB/Al₂O₃ multilayer films, which show significantly enhanced inductance and quality factor at GHz frequencies over their air core counterparts. Good high frequency performance with the inductance over 2nH and the peak quality factor close to 20 was realized in these inductors over a wide operation frequency range of DC ~ 2.5 GHz. By putting these inductors on 0.5 mm thick ferroelectric (011) cut lead magnesium niobate-lead titanate (PMN-PT) slab, we demonstrated a voltage tunable magnetoelectric inductors with a voltage tunable inductance of > 100% ([Gao et al., 2014b](#)).

Optical images of the integrated solenoid inductors are shown in [Fig. 4\(a\)](#) and [\(b\)](#) presents the schematic of tunable inductor. As presented in [Fig. 4\(c\)](#), a high voltage tunability of inductance which reaches up to 100% in about 2–3.5 GHz is achieved. And quality factor tuning corresponding to the same inductor and the same applied electric field is measured and shown in [Fig. 4\(d\)](#). Si substrate was removed by using DRIE and integrated magnetic inductor was bonded with glue to PMN-PT slab that was poled along its thickness direction. The inductance of integrated magnetic solenoid inductors can be approximated by

$$L = \frac{\mu_0 \mu_r N^2 w t_m}{l}, \quad (8)$$

in which N is the total number of turns; and w , t_m , and l are the width, thickness, and length of magnetic film, respectively. And the quality factor Q of an integrated solenoid inductor can be calculated as

$$Q = \frac{\omega \mu_0 \mu_r N t_m w_c \delta (1 - e^{-t/\delta})}{2l\rho}, \quad (9)$$

where ρ is the wire electrical resistivity, w_c , δ and t are the width, skin depth and thickness of the coil, respectively. The performance of all inductors was measured by utilizing a vector network analyzer (VNA) and an RF probing system. All the L and Q values are extracted from transmission line model with s-parameters. The applied E-field ranging from 0 to 8 kV/cm corresponding to a

Power-Efficient Voltage Tunable RF Integrated Magnetoelectric Inductors With FeGaB/Al₂O₃ Multilayer Films. IEEE, pp. 1–4.

voltage across the thickness direction of the PMN-PT slab from 0 to 400 V. Large inductance tunability of $> 100\%$ were achieved in these magnetoelectric inductors with an applied voltage.

Magnetoelectric Filters

Bandpass and bandstop filters are widely used to pass or suppress the signal in a specific frequency range and are critical in signal processing systems (Tu and Chang, 2005; Zhu *et al.*, 2005). Both bandpass and bandstop integrated MEMS filters based on FeGaB/Al₂O₃ magnetic multilayer films were reported in our group (Lin *et al.*, 2016; He *et al.*, 2018). FBAR structures are extensively used in RF bandpass filters, which have very high quality factor, compact size, low loss, preferable temperature stability and processing compatible with the complementary metal-oxide-semiconductor (CMOS) integrated circuit (IC) (Ruby *et al.*, 2001). Based on FBAR resonators with contour mode of transmission, an integrated tunable bandpass filter with FeGaB/AlN magnetoelectric multilayer was realized and a large frequency tunability of ~ 5 kHz/Oe and a high quality factor of 252 were achieved. Traditional ferrite-based bandstop filters mostly rely on the FMR absorption behavior of the magnetic material (Zhu *et al.*, 2009). By taking the advantage of shape anisotropy, a C-band bandstop filter, which was patterned into a slim ribbon shape and fabricated on Si wafer with FeGaB/Al₂O₃ multilayer film under a single transmission line, is reported. A self-resonance at 5 GHz with a high attenuation of over 20 dB was presented and a frequency shift from 5 to over 8.5 GHz was showed by applying a magnetic field up to 400 Oe.

As shown in the schematic of the MEMS ME bandpass filter in Fig. 5(a), the theory of FBAR bandpass filter can be explained by introducing acoustic wave. Specifically, an alternating acoustic wave due to the mechanical resonance can be induced by applying RF electric field to the MEMS resonator. When this acoustic wave transfers to port 2, the dynamic voltage or charge would be generated due to the direct piezoelectric coupling. Fig. 5(c) and (d) present measured return loss S_{11} and insertion loss S_{21} at zero bias field of MEMS ME bandpass filter with increasing magnetic fields. And the results of resonance frequency as a function of DC magnetic fields up to 200 Oe is shown in Fig. 5(b). The shift of the resonance frequency is due to delta-E effect that is the working principle of NEMS ME sensor (Nan *et al.*, 2013). The influence of magnetostrictive strain is much less than that of delta-E effect,

Fig. 5 (a) Schematic of the layered structure of the NEMS ME band-pass filter. (b) Resonance frequency of the NEMS ME band-pass filter as a function of DC magnetic fields. Tunable RF Band-Pass Filters Based on NEMS Magnetoelectric Resonators. IEEE, pp. 1–4.

Fig. 6 (a) Schematic of the bandstop filter. (b) Measured transmission curves of the bandstop filter with 100 nm FeGaB single layer. (c) Measured reflection curves of the bandstop filter with FeGaB multilayers. (d) Measured transmission curves of the bandstop filter with FeGaB multilayers. Reproduced from He, Y., Gao, Y., Chen, H. *et al.*, 2018. Integrated tunable bandstop filter using self-biased FeGaB/Al₂O₃ multilayer thin film. *IEEE Transactions on Magnetics* 54 (9), 1–4.

since the magnetostriction constant of FeGaB of 70 ppm is much smaller than the delta-E effect induced percentage change in Young's modulus which can be up to 20%–30% (Ludwig and Quandt, 2002). The schematic of the bandstop filter device is shown in Fig. 6(a), in which the dimension of the rectangular co-planar waveguide (CPW) is 8 mm × 3.2 mm. The operating frequency corresponding to FMR frequency is determined by the external magnetic field and the in-plane uniaxial anisotropy field in this case. The FMR frequency of the magnetic material layer is given in the following equation:

$$f_{\text{FMR}} = \gamma \sqrt{(H_{\text{dc}} + H_a + (N_y - N_z)4\pi M_s)(H_{\text{dc}} + H_a + (N_x - N_z)4\pi M_s)}. \quad (10)$$

in which, γ represents the gyromagnetic ratio; H_{dc} is the applied magnetic field along the length direction; H_a denotes the anisotropy field induced by the applied field during film deposition; N_x , N_y , and N_z are the demagnetizing factors determined by the dimensions of the magnetic layer; x , y , and z are the width, height, and length direction, respectively; and M_s is the saturation magnetization.

The magnetic tunability was obtained by applying varied external magnetic fields that were parallel to the magnetic ribbon. Transmission curves of the bandstop filter with a 100 nm-thick FeGaB single layer were measured and presented in Fig. 6(b). The device shows a wide tuning range from 3.9 to 9.3 GHz with a magnetic field of up to 400 Oe. In order to reduce the insertion loss due to eddy-current effect, the magnetic material was deposited as multilayer with more periods. The results for reflection and transmission curves of the bandstop filter with multilayer structure were shown in Fig. 6(c) and (d).

Magnetoelectric Antennas

Nitsan (1977) published the very first paper, which explored the detection of RF electromagnetic radiation (EMR) from fracture of quartz-bearing rocks and other hard piezoelectric materials, that is related to ME antennas. Weldon *et al.* (2008) presented a design method for a highly integrated carbon nanotube radio transmitter in 2008, which radiates high frequency EM waves by exploiting charge on tip of the vibrating nanotube and acts like a small antenna. Besides, the acoustic wave-mediated multiferroic antennas

that are comprised of magnetostrictive/piezoelectric heterostructures was firstly proposed and described theoretically by Yao *et al.* (2015). Mateen *et al.* (2016) successfully demonstrated the wireless actuation of micro-sized silicon-based piezoelectric resonators with resonance frequencies of 36 MHz and 121 MHz at power levels of nanowatts and distance of ~ 3 feet by using conventional piezoelectric resonators. From 2017, various authors published their works on mechanical antennas of VLF and ULF frequencies by utilizing spinning magnets (Selvin *et al.*, 2017; Fawole and Tabib-Azar, 2017; Bickford *et al.*, 2017; Prasad *et al.*, 2018). Chu's limit and lower bound of the radiation quality factor were proven to be broken by the proposed spinning magnet antenna. The unprecedented demonstration of ultra-compact ME NEMS antennas was proposed by us in 2017 (Nan *et al.*, 2017) and was expected to have great impacts on our future antennas and communication systems for internet of things, wearable antennas, bio-implantable and bio-injectable antennas, smart phones, wireless communication systems, etc. The new ME antennas based on ME nano-plate resonator (NPR) and thin-film bulk acoustic resonator (FBAR), which are one to two orders of magnitude smaller than state-of-the-art compact antennas, have a novel receiving and transmitting mechanism.

COMSOL was used to design both ME NPR and FBAR based antennas in this work. The resonant bodies of these NEMS ME resonators, which are composed of piezoelectric and magnetostrictive element for the ME heterostructure, were patterned with 500 nm AlN and $[\text{Fe}_7\text{Ga}_2\text{B}_1 (45 \text{ nm})/\text{Al}_2\text{O}_3 (5 \text{ nm})] \times 10$ (hereafter termed FeGaB) thin film ME heterostructures fully suspended on a Si substrate. Efficient on-chip acoustic transduction with ultra-low energy dissipation can be achieved with the use of a NEMS resonator with an ultra-thin 500 nm AlN thin film enables. In this work, a wide range of frequencies from 60 MHz to 2.5 GHz can be realized by using a geometric design of the demonstrated ME antennas that exhibit different mode of vibrations.

NPR ME Antennas

Fig. 7(a) presents the schematic of ME NPR which has a rectangular resonating plate and the measurement structures. And the SEM image of the NPR ME resonator that consists of a single-finger bottom Pt electrode and a thin film FeGaB/AlN heterostructure is shown in Fig. 7(b). All the fabrication processes of devices in this work were compatible with CMOS microfabrication processes.

(c) Admittance curve and MBVD model fitting of the ME NPR. The inset shows the schematic of the cross-section of the ME heterostructure. (d) Finite element analysis (FEA) of ME NPR for the admittance amplitude. The inset shows the in-plane displacement of the nano-plate at resonance peak position and its coordinate system. (e) Admittance curve of a non-magnetic control sample which has the same device design as ME NPR. The inset shows the schematic of the device cross-section. (f) ME coupling coefficient (left axis) and the induced ME voltage (right axis) versus frequency of RF magnetic field excitation. (g) FEA of ME NPR for the induced ME voltage measurement. The inset shows the in-plane displacement excited by RF magnetic field. (h) Induced voltage versus frequency for the non-magnetic device. The inset illustrates the zoomed-in view of the resonance peak area (red circle). Reproduced from Nan, T., Lin, H., Gao, Y., *et al.*, 2017. Acoustically actuated ultra-compact NEMS magnetoelectric antennas. *Nature Communications* 8 (1), 296.

The length L and width W of the rectangular resonating plate are $200\ \mu\text{m}$ and $50\ \mu\text{m}$, respectively. By fully releasing the nano-plate from the Si substrate but electrically contacted with the two anchors, we can optimize ME coupling with a minimum substrate clamping effect. As shown in Fig. 7(c), the characterization of the electrical admittance curve was presented to study the electromechanical properties of the ME NPR. By utilizing the MBVD model, an electromechanical resonance frequency $f_{r,\text{NPR}}$ of $60.68\ \text{MHz}$, a high quality factor (Q) of 930 and electromechanical coupling coefficient k_t^2 of 1.35% are given. This electromechanical resonance frequency, which can be analytically expressed as $f_{r,\text{NPR}} \sim \frac{1}{2W_0} \sqrt{\frac{E}{\rho}}$, corresponds to the contour mode of vibration excited in AlN, where W_0 is the width of the resonator pitch, E and ρ are the equivalent Young's modulus and equivalent density of the FeGaB/AlN resonator respectively. Finite element analysis (FEA) on the admittance curve of the device with the same geometry is shown in the Fig. 7(d), which is in good agreement with Fig. 7(c). The in-plane displacement distribution is shown in the inset in Fig. 7(d), which indicates a contour extensional mode of vibration. It is worth noting that the Q -factor of this NPR is much higher than the traditional LF ME heterostructures in previous reports (Srinivasan *et al.*, 2005; Greve *et al.*, 2010a; Jahns *et al.*, 2013).

As shown in Fig. 7(f), an UHFIL is used to measure the induced ME voltage of the NPR device, which is excited by an RF magnetic field (H_{rf}) with an amplitude about $60\ \text{nT}$. A clear electromechanical resonance peak is shown in the ME voltage spectrum at $60.7\ \text{MHz}$ with a peak amplitude of $180\ \mu\text{V}$. The output ME voltage spectrum measured experimentally agrees well with the FEA results with a peak amplitude of $196\ \mu\text{V}$ as shown in Fig. 7(g), the inset of which shows the simulated in-plane displacement of the ME resonator. A high ME coupling coefficient under zero DC bias magnetic field, which is expressed as $\alpha = \partial U / (\partial H_{\text{rf}} \cdot d) = 6\ \text{kV Oe}^{-1}\ \text{cm}^{-1}$, can be acquired at the electromechanical resonance frequency, where U is the induced ME voltage, and d is the thickness of AlN layer. A control sample of non-magnetic single-finger NPR has also been fabricated as a comparison and tested to confirm that the observed voltage output is due to the strain-mediated ME coupling. As shown in Fig. 7(e) inset, the non-magnetic resonator was formed by depositing a $500\ \text{nm}$ Cu thin film instead of FeGaB thin film on AlN plate. A similar admittance behavior of the Cu/AlN based control sample as the ME NPR was observed in Fig. 7(e). However, the induced voltage of the control sample operating at electromechanical resonance that is shown in Fig. 7(h) is very low under the same excitation condition ($H_{\text{rf}} = 60\ \text{nT}$), about two orders of magnitude smaller than the induced voltage in the FeGaB/AlN ME NPR.

FBAR ME Antennas

Based on the thickness resonance mode of FeGaB/AlN thin film, the UHV ME FBARs operate at $2.53\ \text{GHz}$. The active element of ME FBAR antenna is a suspended FeGaB/AlN ME circular disk with a diameter of $200\ \mu\text{m}$ as shown in Fig. 8(a) and (b). The electromechanical resonance frequency ($f_{r,\text{FBAR}}$) of the ME FBAR, which is different from ME NPR, is defined by the thickness of the

Fig. 8 ME FBAR antennas. (a) Schematic of the antenna measurement setup. (b) SEM images of the fabricated ME FBAR. (c) Return loss curve (S_{22}) of ME FBAR. The inset shows the out-of-plane displacement of the circular disk at resonance peak position. (d) Transmission and receiving behavior (S_{12} and S_{21}) of ME FBAR. (e) Return loss (S_{22}) curve of the non-magnetic Al/AlN control FBAR. (f) Transmission and receiving behavior (S_{12} and S_{21}) of the non-magnetic Al/AlN control FBAR. Reproduced from Nan, T., Lin, H., Gao, Y., *et al.*, 2017. Acoustically actuated ultra-compact NEMS magnetoelectric antennas. *Nature Communications* 8 (1), 296.

circular resonating disk and can be expressed by $f_{r,FBAR} \sim \frac{1}{2T} \sqrt{\frac{E}{\rho}}$, where T is the total thickness, E is the effective Young's modulus, and ρ is the effective density of the FeGaB/AlN heterostructure disk. Fig. 8(c) presents the measured $f_{r,FBAR}$ of 2.53 GHz, peak return loss of 10.26 dB and a Q-factor of 632 by measuring the reflection coefficient (S_{22}) of the FBAR device. The out-of-plane displacement of the FBAR is simulated and presented in Fig. 8(c) inset, which indicates a thickness extensional mode. Fig. 8(d) shows the receiving and transmitting behavior of ME FBARs that corresponds to the S_{21} and S_{12} parameters, respectively. It is obvious that S_{12} and S_{21} curves nearly overlap with each other, in which a strong resonance peak is observed at $f_{r,FBAR}$. By using the measured S_{12} data, the antenna gain of the ME FBAR is measured to be -18 dBi at $f_{r,FBAR}$ through gain comparison method. As a control device for ruling out the artificial EM coupling to the ground loop, a non-magnetic Al layer with thickness of 1000 nm was deposited to replace the 500 nm thick FeGaB multilayer for keeping the resonance frequency unchanged. Fig. 8(e) shows a similar electromechanical property of the non-magnetic control device as ME FBAR. The weak S_{21} and S_{12} resonance peaks, which are observed at 2.5 GHz in Fig. 8(f), suggest that the ME coupling effect dominates in the S_{21} and S_{12} measurement results of the ME FBAR antenna.

Challenges and Opportunities

Although lots of studies have been done on the magnetoelectric composites in the past years, there are still many challenges and opportunities that need to be addressed in the coming years. From the science point of view, understanding, modeling, and controlling of ME interaction are of critical importance for the community. Development of new mechanisms for ME composites is desired as well for approaching the limit of strength of ME coupling. From the materials point of view, large piezoelectric and magnetostrictive coefficients are always in demand for the whole multiferroic society. And in order to have high-performance and high-frequency devices, growth of thick and epitaxial films is required for stronger ME coupling. Besides, fabrication and measurements of micro/nano-magnetoelectric composites are of great interest for future applications in micro/nano-electronics. From the technology point of view, integration and scale-up with existing silicon processing flows and electronics are in particular key challenges and valuable.

The bandwidth of ME composites based devices is narrow, which limits their working frequency range, because the natural resonant peak around the resonance frequency is sharp. The broadband/wideband performance is desired for some applications such as ME antennas and is characterized by flat ME response. There are very limited efforts that have been made to this area although some papers were published (Yu *et al.*, 2005; Park *et al.*, 2009; Park and Priya, 2012; Rajaram Patil *et al.*, 2013). The bandwidth performance of a combined structure with several Terfenol-D/PZT bilayers through parallel and series connection was measured by Yu *et al.* Compared with a single bilayered structure, the frequency response to external field was much wider and the ME coupling far from the resonance ranges was significantly enhanced (Yu *et al.*, 2005). The ME response over a broad DC bias magnetic field range was found to be almost unchanged by adjusting variables that affect ME coefficient including the size and shape of laminates, the number of layers, etc. (Park *et al.*, 2009). A DC bias field is commonly needed in most conventional ME composites in order to obtain the maximum ME coefficient. Therefore, permanent magnets or electromagnets are required in the system, which result in bulky devices and electromagnetic interference. To solve these problems and facilitate ME devices miniaturization for integrated electronics and medical applications, self-biased ME composites are introduced and there is no need for DC magnetic field anymore. Zhou *et al.* recently presented a review with a comprehensive understanding of the self-biased ME composites. Readers can also refer to (Zhou *et al.*, 2016) for the properties of different types self-biased ME composites according to their working principles. All of these issues are both challenges as well as opportunities for the future applications.

Varistors

One of the first, and most established, applications of ZnO in electronics is that of varistors for voltage surge protection in high voltage systems. Such circuits are subject to occasional transient overvoltages (from, for instance, lightning or switching) which can cause equipment failure. Varistors are devices which have a high electrical resistance for low applied voltages, which decreases as the voltage is raised. When placed in parallel with a piece of electrical equipment, varistors thus provide a circuit breaker effect at high voltages. In the case of ZnO varistors, this is achieved by means of the double Schottky junctions which form naturally at the pronounced grain boundaries in sintered ZnO powders (Fig. 1), and which act as a collection of back-to-back Zener diodes. Due to the relatively high melting point of ZnO ($\sim 1975^\circ\text{C}$), such varistors can support the heating associated with large current flow. ZnO displaced SiC as the dominant varistor material when it was discovered that doping ZnO with metal oxides (of, for instance, Bi, Pr, Co or Mn), which segregate to the grain boundaries, gives the most non-linear I/V characteristics known so far (typically showing resistivities of more than $10^{10} \Omega \text{ cm}$ below the breakdown voltage and several $\Omega \text{ cm}$ above the breakdown voltage) (Matsuoka, 1971).

Optical Filtering

Another mature use of ZnO in electronics/photonics applications is as an optical filter. Indeed, the wide bandgap ($E_g = 3.37 \text{ eV}$) that gives excellent optical transparency right across the visible spectrum also inherently blocks UV light (Fig. 2).

Based on this (along with low cost fabrication and excellent biocompatibility) ZnO has found application in UV filter coatings (e.g., for welding glasses) and as the UV blocking component in the new generation of transparent sun creams. Indeed, the latter is currently one of the biggest industrial applications of nanoparticles. This is based on ZnO's propensity for being nanostructured, combined with the fact that ZnO nanoparticles under $\sim 100 \text{ nm}$ in diameter (such as those in Fig. 3) do not scatter visible light.

ZnO coatings/pigments have also been used to boost the energy efficiency of windows/paints during hot weather by reflecting infrared (IR) solar heat and thus reducing the need for air conditioning (Fang *et al.*, 2013). This is because the plasma frequency can be engineered down (through increased doping) so as to reflect IR radiation.

Transparent Conductors

Wurtzite ZnO is also a semiconductor material with a resistivity that can be tailored from semi-insulating right through to semi-metallic by doping. Hence, under appropriate growth conditions, ZnO can be simultaneously transparent and highly electrically conducting (i.e., a "Transparent Conducting Oxide" (TCO)). TCOs are a family of degenerately-doped n-type semiconductors with resistivities under about 10^{-3} ohm cm , free-electron concentrations of the order of 10^{20} cm^{-3} and average transmittances $> 80\%$ for the whole visible range. Up till present, the most widely used TCO has been Sn-doped In_2O_3 (ITO). Doped ZnO is currently displacing ITO, however, for applications such as anti-electrostatic-discharge layers, electromagnetic interference shielding, transparent wiring, touch-sensitive panels and transparent electrical contacts (for use in flat panel displays, solar cells, light emitting diodes (LEDs) etc.) .

This is because zinc is cheaper, more abundant and less toxic than indium, while ZnO is easier to process, shows superior resistance to hydrogen plasmas and can be fabricated at lower temperatures (Gordon, 2000). Moreover, the mobilities and conductivities attainable with degenerately doped ZnO (typically with Al, Sn, Ga or Si) have become comparable with those for ITO (Fig. 4).

Doping with F, on the other hand, gives ZnO the highest optical transparency and the lowest plasma frequency of all TCOs while doping with Al can give transparencies into the mid IR (Dhakal *et al.*, 2012) (Table 1).

Solar

Many solar cell technologies employ at least one ZnO-based layer. As well as acting as transparent electrodes the ZnO layers often play a number of critical roles, including being an electron reservoir, an electron transport layer, a template/buffer for growth of the succeeding layer and a light management layer (anti-reflection (AR) and light trapping surfaces/interfaces profiting from the relatively high refractive index (2.0) of ZnO) (Fig. 5). The ZnO thickness, positioning, conductivity and morphology are thus integral to the cell design, and often represent a significant proportion of overall PV structure (& its' cost) (Fig. 6).

Fig. 1 Scanning electron microscope (SEM) image of a granular ZnO microstructure ($\sim 10\ \mu\text{m}$ diameter grains) with pronounced grain boundaries.

Fig. 2 Optical transmittance spectra illustrating the high intrinsic transparency in the visible range of an epitaxial ZnO film grown on a c-plane sapphire substrate.

Fig. 3 SEM image of sun-cream-scale ZnO nanoparticles fabricated using a low-cost wet chemical growth approach.

As well as being the case for a number of established solar cell technologies (eg amorphous silicon (*a*-Si), polycrystalline silicon, CdTe/CdS and chalcopyrite Cu-In-Ga-Se based thin film photovoltaics), the above is also true for several emergent technologies, including hybrid inorganic/organic cells, Quantum Dot Sensitized Solar Cells (which both use ZnO nanowires for electron transport) and some variants of tandem silicon/perovskite solar cells.

Fig. 4 The evolution of the state-of-the-art resistivity for alloys of SnO_2 , In_2O_3 and ZnO over time. After Minami, T., 2005. Transparent conducting oxide semiconductors for transparent electrodes. *Semicond. Sci. Technol.* 20, 35–44.

Table 1 Best of class crystalline materials for transparent conducting applications

Property	Material
Highest transparency	ZnO:F , Cd_2SnO_4
Highest conductivity	$\text{In}_2\text{O}_3\text{:Sn}$
Lowest plasma frequency	$\text{SnO}_2\text{:F}$, ZnO:F
Highest plasma frequency	Ag , TiN , $\text{In}_2\text{O}_3\text{:Sn}$
Highest workfunction, best contact to p-Si	$\text{SnO}_2\text{:F}$, ZnSnO_3
Lowest workfunction, best contact to n-Si	ZnO:F
Best thermal stability	$\text{SnO}_2\text{:F}$, TiN , Cd_2SnO_4
Best mechanical durability	TiN , $\text{SnO}_2\text{:F}$
Best chemical durability	$\text{SnO}_2\text{:F}$
Easiest to etch	ZnO:F , TiN
Best resistance to H plasmas	ZnO:F
Lowest deposition temperature	$\text{In}_2\text{O}_3\text{:Sn}$, ZnO:B , Ag
Least toxic	ZnO:F , $\text{SnO}_2\text{:F}$
Lowest cost	$\text{SnO}_2\text{:F}$

Note: Gordon, R.G., 2000. Criteria for choosing transparent conductors. *MRS Bull.* 25, 52–57.

Transparent/Flexible Electronics

Over recent decades, a new kind of ZnO-based TCO has emerged. These are Amorphous Oxide Semiconductors (AOS) (Hosono, 1996). Compared to wurtzite ZnO, amorphous ZnO-based alloys have lower processing temperatures, are cheaper to fabricate in large area format, are lighter and have better uniformity of properties (due, in part, to a lack of grain boundaries and related issues). Importantly, their performance is also stable/reproducible during and after repetitive bending, so they are compatible with flexible substrates/electronics.

Although AOS are not a novel class of materials (Denton *et al.*, 1954), the new generation of ZnO-based AOS exhibits enhanced carrier mobility, superior capacity for processability in air and improved thermodynamic stability compared with conventional Covalent Amorphous Semiconductors (CAS) and existing AOS (Nomura *et al.*, 2004).

Amorphous InZnO (a-IZO) is considered the most representative ternary AOS system (Wager *et al.*, 2014; Kim *et al.*, 2011). The resistivity of a-IZO can be varied very widely (from 10^{-4} to $10^8 \Omega \text{ cm}$) by controlling the cation composition and cation/oxygen stoichiometry (Kwon and Jeong, 2015). a-IZO can exhibit a mobility over $50 \text{ cm}^2/\text{Vs}$ and doping with Sn can produce even higher mobilities ($> 100 \text{ cm}^2/\text{Vs}$; Kim *et al.*, 2010) along with transparencies that are comparable with ITO (Sashabayashi *et al.*, 2003). Thus AOS are viable alternatives for use in transparent electrode applications (Minami *et al.*, 1996).

With regards to the origin of this remarkable property set, Hosono (1996) proposed, that the relatively high mobilities observed in AOS compared with CAS may be obtained because of differences in the intrinsic nature of the chemical bonding. Figs. 7 and 8 illustrate the wavefunction at the bottom of the conduction bands in CAS and AOS.

It can be seen that the hybridized sp^3 orbital overlap in CAS is highly directive. Therefore, any bond angle fluctuations would be expected to significantly alter the electronic levels, and carrier transport should be controlled by hopping between localized tail-states rather than band conduction. Thus structural randomness could greatly degrade the carrier mobility. Nomura *et al.* (2004)

Fig. 5 The upper images show the aspect of a silicon wafer before and after coating with a ZnO moth-eye nanostructure (shown in the underlying SEM image). This sub-visible-wavelength scale of moth-eye nanostructure shows excellent high angle and broad-band AR performance by combining graded effective refractive index and nanostructure side-wall reflections so as to maximize light incoupling, as shown on the left and right, respectively, in the lower schematic. After Peres, M., Soares, M., Neves, A., Monteiro, T., Sandana, V., 2010. Morphological and optical studies of self-forming ZnO nanocolumn & nanocone arrays grown by PLD on various substrates. *Phys. Status Solidi A* 1–4. Raut, H.K., Ganesh, V.A., Nair, S., Ramakrishn, S., 2011. Anti-reflective coatings: A critical, in-depth review. *Energy Environ. Sci.* 4, 3779–3804.

explained that AOS, in contrast, have higher ionicity and the bottom of the conduction band has extended spherical s orbitals associated with the metal ion. These electronic levels have an overlap which is relatively insensitive to distortion of the metal–oxygen–metal chemical bonds. Thus strain and disorder within the material should not strongly impact the conduction. It was proposed, therefore, that AOS materials can show degenerate band conduction and superior electron mobility compared with CAS. More recently, however, this hypothesis was put into question because it was reported that trap-free mobilities are comparable for a-Si:H and AOS. Thus a more pronounced electron trapping in a-Si:H is put forward as the origin of the difference in mobility (Stewart *et al.*, 2016). Bond-angle variability (a-Si:H) and cation sublattice disorder (a-IGZO) are proposed as the respective origins of the carrier trapping.

Recently, a new generation of TFTs, employing such amorphous ZnO-alloys as channels, has been developed. Fig. 9 illustrates a typical “staggered bottom gate” oxide TFT architecture.

This is an analogy of an n-channel Metal Insulator Semiconductor Field Effect Transistor (MISFET) with an AOS substituted for both the metal gate and the semiconductor channel. Walter Shockley explained the function of MISFETs in 1950: “a very thin layer of semiconductor is placed on an insulating support. This layer of semiconductor constitutes one plate of a parallel-plate capacitor. If this capacitor is charged, with the metal plate positive, then the additional charge on the semiconductor will be represented by an increased number of electrons. Consequently, the added electrons should be free to move and should contribute to the

Fig. 6 A schematic and a cross-sectional electron microscope image of a high performance “micromorph” silicon tandem solar cell based on a combination of amorphous and polycrystalline silicon light harvesting layers. Of note is that (a) the ZnO-based layers represent a bigger proportion of the cell than the silicon (b) the ZnO-based layers play a number of critical light management roles (transparency, anti-reflection surfaces and light trapping interfaces) (c) the ZnO has to be an appropriate/compatible crystallographic template for the overgrowth of the succeeding silicon layer and (d) the thickness, doping/conductivity and morphology of the various ZnO layers are an integral part of the overall solar cell conception/design/realization. Reproduced from Söderström, T., Dominé, D., Feltrin, A., *et al.*, 2010. ZnO Transparent conductive oxide for thin film silicon solar cells. Proc. SPIE 7603, (76030B-8).

Fig. 7 Schematic of the electron orbitals at the bottom of conduction band in CAS. After Nomura, K., Ohta, H., Takagi, A., *et al.*, 2004. Room-temperature fabrication of transparent flexible thin-film transistors using amorphous oxide semiconductors. Nature 432, 488–492.

conductivity of the semiconductor. In this way, the conductivity in the semiconductor can be modulated by the voltage put on the capacitor plate. Since this input signal requires no power if the dielectric is perfect, power gain will result”.

Although oxide TFTs are not a novel concept (Boesen and Jacobs, 1968; Ohya *et al.*, 2001), the new generation exhibits much higher on-off ratios ($>10^8$) and channel mobilities than the hydrogenated amorphous silicon (a-Si:H) based devices which are currently used for many state-of-the-art microelectronics applications (including that of the channel in “select transistors” which

Fig. 8 Schematic of the electron orbitals at the bottom of the conduction band in ZnO-based AOS. Spheres denote metal s orbitals. The contribution of oxygen 2p orbitals is small. Overlap of neighboring s orbitals is rather large, and is not significantly affected even in an amorphous structure. After Nomura, K., Ohta, H., Takagi, A., *et al.*, 2004. Room-temperature fabrication of transparent flexible thin-film transistors using amorphous oxide semiconductors. *Nature* 432, 488–492.

Fig. 9 Schematic of a generic “Staggered Bottom-Gate” oxide TFT. In this case, the semiconductor channel and conducting gate are both constituted of an AOS.

Fig. 10 Output characteristic of a ZnO channel TFT showing relatively large I_d , enhancement mode operation (no power consumption when off), good pinch off and hard saturation plateauing of I_d which indicates that the channel was depleted of carriers.

Fig. 11 Schematic of a paper “Interstrate” TFT.

transmit or block backlight for each pixel in Liquid Crystal Displays (LCD)). Another key advantage of oxide TFTs is that they are (low leakage) enhancement mode devices (Fig. 10).

This is preferable to the depletion mode alternative since circuit design is simpler and power dissipation is lower (because the off-state is the power-down state).

In contrast to TCO applications, the channels in TFTs need as low a carrier concentration as possible in order to achieve stable performance (Kwon *et al.*, 2004) - ideally $< \sim 10^{14} / \text{cm}^3$, according to Nomura *et al.* (2004). This can be achieved by introducing an extra component to a-IZO in order to suppress excessive carriers. Gallium (Ga) is the most common carrier suppressor adopted for the a-IZO system. (Nomura *et al.*, 2006; Barquinha *et al.*, 2008) and a-IGZO has become the industry standard channel for oxide TFTs.

However, gallium addition also suppresses the relatively high carrier mobility ($> 20 \text{ cm}^2/\text{Vs}$; Hosono, 2006) that can be obtained in In-rich amorphous a-IGZO (Orita *et al.*, 2001). Thus a compositional trade-off is required and state-of-the-art a-IGZO based TFTs typically have a mobility of about $12 \text{ cm}^2/\text{Vs}$ (Wager, 2016), as compared with a value of $< 1 \text{ cm}^2/\text{Vs}$ for a-Si:H. TFTs made with a-IGZO channels also offer the advantages of excellent performance when fabricated at room temperature which resolves the existing trade-off between processing temperature and device performance and allows fabrication on inexpensive heat-sensitive substrates such as transparent polymers or paper (a-Si:H fabrication temperature is too high for many flexible substrates).

As a result of these attributes a-IGZO based TFTs offer several decisive advantages over the incumbent a-Si:H based devices for use as backplane select transistors in OLED and active matrix LCD screens. The higher mobility of oxide TFTs offers increased refresh rates and the wide bandgap reduces light sensitivity (lower noise) and degradation. Improved transparencies allow more backlight to be transmitted through each pixel in LCD screens, yielding a brighter and more efficient (lower power consumption) display. This also means that the aperture ratio can be reduced, so as to give smaller pixels and thus higher resolution. Finally, ZnO based TFTs can support higher device currents. This offers possibilities for higher power operation. Since emerging in 2012, commercial a-IGZO based oxide TFTs have moved rapidly into mass production (using both physical and chemical vapor deposition fabrication) for use in phones, monitors, tablets, laptops, desktop PCs, and TVs (Wager, 2016). With regards to the future, a significant trend in oxide TFTs is towards the use of non-toxic and non-resource-critical (sustainable) materials. Hence, In- and Ga-free alternatives are being explored. a-ZnSnO (a-ZTO) in particular is showing promising results (Avis and Jang, 2011). Another active development front is that of novel device architectures. Fig. 11 shows a Metal Oxide FET (MOSFET) in which the paper acts as both the dielectric and the support, or “interstrate” (Martins *et al.*, 2008; Fortunato *et al.*, 2008) for use in oxide TFT based “e-paper” (Ito *et al.*, 2007).

A further device architecture innovation is ZnO-based Metal Semiconductor FETs (MESFETs) (Frenzel, *et al.*, 2008). These devices can operate in a lower voltage regime ($+/- 1\text{V}$) compared with MISFETs. Thus, they should be better suited to driving display pixels. A method to obtain fully transparent MESFETs devices (including all contacts) has also been developed. This methodology can be adapted to crystalline and amorphous substrates and films.

Light Emitters

A long-established, application exploiting light emission from ZnO is that of a green/blue phosphor. This is based on the efficient oxygen vacancy defect emission (peaked at about 490 nm) which is observed for zinc-rich ZnO (Fig. 12).

This phosphor was very widely used in vacuum fluorescent displays in the late 20th century but the market has waned in recent years due to the advent of novel display technologies.

More recently ZnO has been widely investigated as a potentially superior UV emitter to GaN (currently the commercially predominant wide bandgap opto-semiconductor). This is because the higher stability of the ZnO free exciton, which has a binding energy of 60 meV (compared to 21 meV for GaN) (Klingshirn, 2007) should allow much brighter UV emitters with lower threshold voltages (Gadallah *et al.*, 2013). A fundamental challenge in this respect, however, is the lack of the p-type ZnO which is necessary for the manufacture of efficient p-n junction devices (Tang *et al.*, 2017). This is because (a) it has proven difficult to incorporate and activate sufficient acceptor concentrations (the main acceptor dopants attempted have been the Group V elements N, P, As, Sb plus the Group Ia elements Li, Na, K and the Group Ib elements Ag, Cu, Au – there are various competing theories as to how the dopants act) and (b) background donors tend to compensate the acceptors because native defects (O vacancies and Zn interstitials) in combination with common impurities (such as H, Al and Ga) act as shallow donors. Advances in ZnO epitaxial growth along with the development of high quality single crystal ZnO substrates (Maeda *et al.*, 2005) and the adoption of higher purity sources have, however, helped to suppress defect densities and non-intentional impurity doping respectively and thus reduce donor compensation.

Fig. 12 SEM image of a zinc-rich ZnO nanowall sample with a photograph of the corresponding photoluminescence (inset) showing a typical green/blue emission peaked at about 490 nm.

Although many groups have nevertheless reported the development of p-type ZnO (Fan *et al.*, 2013; Tang *et al.*, 2017) allowing the demonstration of light-emitting p–n junctions (Rahman, 2019) experimental results generally show mobilities, conductivities and overall device efficiencies that are relatively disappointing. An emerging factor is that Mg alloying could facilitate the task of p-type doping. The two main reasons put forward for this are the shifting of the conduction band to higher energy acting to reduce the background donor concentration and the Zn vacancy (acceptor) concentration increasing with Mg content. In another approach, many groups have demonstrated transparent p–n junction devices using alternative p-type layers (Rahman, 2019), including p-GaN (Bayram *et al.*, 2008; Rogers *et al.*, 2006), p-NiO (Fig. 13), p-Cu₂O and p-SnO and p-Si, (Pau *et al.*, 2010; Rogers *et al.*, 2009).

These are not ideal in terms of band alignment (and, therefore, carrier injection), however, and the conductivities/mobilities of the p-type TCO are relatively low, which hinders device performance.

Sensors

The longest established use of ZnO for sensing is in gas detectors. This is because the surface and grain boundaries of ZnO are depleted of electrons because of absorbed oxygen. Exposure to oxidizing or reducing gases modulates this carrier depletion layer and hence causes the conductivity to either rise or fall (Fig. 14). The first commercial devices employed sintered ZnO powders because they were inexpensive and gave a competitive sensitivity combined with high mechanical/chemical stability and low toxicity. Recently, new generations of higher sensitivity epitaxial (Rombach *et al.*, 2016) and nanostructured ZnO gas sensors are emerging (Arafat *et al.*, 2012). The epitaxial sensors are engineered to have higher performance by presenting only the most sensitive crystallographic plane to the gas. Such epitaxial layers could also have further advantages over polycrystalline samples such as increased stability and higher sensing speed.

The nanostructured sensors, on the other hand, rely on their intrinsically large surface-to-volume ratio to provide compact, low-power devices with sub-parts-per-million (ppm) sensitivity capability for a number of molecules, including C₂H₅OH, CO, H₂, H₂O, H₂S, NH₃, NH₄, NO₂ and O₃. There has also been progress in developing innovative ZnO-based gas sensors which function at room temperature (Zhu and Zeng, 2017).

Wurtzite ZnO also offers a polar crystal structure with amongst the highest piezo-responses of any semiconductor (Triboulet, 2000). Furthermore, sputtered ZnO films show better quality and adherence to a-SiO₂/Si than alternative materials with larger piezo-responses. This capacity for monolithic integration with silicon-based electronic circuitry, along with an amenability to chemical processing, has led to ZnO being adopted for use as the piezoelectric transducer layer in surface acoustic wave (SAW) devices, which are well established for multiplexing/demultiplexing bandpass filtering for telecommunications applications: primarily cellular phones and base stations.

More recently ZnO-based SAW devices have been adopted for a whole range of sensing applications (bio, gas, humidity, UV light, pressure, chemical) (Constantinoiu and Viespe, 2020). For sensing applications, reducing or oxidative analyte molecules interact with the free electrons on the ZnO surface and thus impact the velocity of the SAW.

SAW sensors are typically based a pair of Inter-Digitated Transducers (IDTs) deposited on an piezoelectric layer. The IDTs are comprised of periodic ($\lambda/4$) metallic electrodes in the form of two intercrossing combs (Fig. 15). Their function is to convert a periodic input electrical signal into a SAW on the piezoelectric surface and then back to a periodic electrical signal at the output IDT. Changes in SAW velocity modify the transmission delay between the input and output signals.

Compared to other sensor technologies, SAW sensors offer high sensitivity, short response/recovery times, small size, low cost, and the possibility of wireless operation.

Moreover, these devices also offer the advantage that the challenges of processing, contacting and packaging ZnO based SAW devices on an industrial scale have already been mastered (Kadota, 2005).

Toulouse). The elevated temperature operation is applied in order to overcome a surface activation energy barrier and increase the reaction kinetics.

Fig. 15 Schematic and photograph of an Inter-Digitated Transducer SAW device fabricated by UV photolithography of gold contacts on a ZnO layer grown on a quartz substrate. Reproduced from Zerdali, M., Bechiri, F., Hamzaoui, S., *et al.*, 2017. Identification of acoustic waves in ZnO materials by Brillouin light scattering for SAW device applications. Proc. SPIE 10105, (1010514-1).

Recently, the use of ZnO as a UV photodetector (PD) has received much attention. This is because the bandgap can be tuned from the UVA into the UVC (solar blind region) by alloying with MgO (while maintaining the semiconducting wurtzite phase).

Current state-of-the-art (Mg)ZnO PD are usually based on Metal-Semiconductor-Metal (MSM) IDT architectures (Yang *et al.*, 2017; Rogers *et al.*, 2013). An MSM-PD is made by forming two ("back-to-back") Schottky electrodes on the surface of an n-type (Mg)ZnO layer in the form of a single IDT. Under a DC voltage bias operation one of the electrodes is always reverse biased and blocks current flow unless above-bandgap (ie UVC) light impinges on the sample so as to produce photo-generated charge carriers and increase the electrical conductivity (Fig. 16).

As well as low dark currents, such PD exhibit sharp wavelength cut-off, high speed operation, linear signal response with optical power and extremely low parasitic capacitance/noise. UVC devices, such as that in Fig. 16 are of particular interest because of their solar blindness. These characteristics make them attractive for sensing and imaging applications (e.g., aerospace, automotive, military, petroleum, flame detection and astronomy). The main challenges are to compete with alternative solid state UVC PD

Fig. 16 The upper image shows IV characteristics for a 275 nm (Mg)ZnO MSM photodetector with/without front illumination. The lower figure compares plots of the bandgap vs. lattice constant for wurzite (Al,In)GaN and (Mg,Cd)ZnO. UV bandgap engineering of ZnO (up to 10.6 eV) can also be achieved effectively by alloying with BeO. There are toxicity and handling issues in this case, however. Reproduced from Rogers, D.J., Teherani, F.H., Sandana, V.E., *et al.*, 2018. The new oxide paradigm for solid state ultraviolet photodetectors. *Proc. SPIE 10533*, (105331P-1). Rogers, D.J., Bove, P., Sandana, E.V., Razeghi, M., Teherani, F.H., 2013. ZnO moves further into the UV. *Laser Focus World* 49 (10).

based on SiC (already available) and (Al)GaN (emerging). However, the insertion of high pass filters is necessary with SiC (bandgap engineering is not possible) and UVC (Al)GaN detectors are difficult/expensive to fabricate.

ZnO is also emerging for biosensing. As well as SAW-based sensors these can be chemoresistive, optical/plasmonic, or FET-based transducers (Pearton *et al.*, 2010). Good electrical conductivity, chemical stability, a biomimetic nature, the potential for surface functionalization, biocompatibility (the biological activity of the element to be recognized should be retained) along with a high isoelectric point, of 9.5 (which facilitates immobilization of biomolecules through an electrostatic interaction) make ZnO an attractive biosensor matrix.

Amongst these, nanostructure-based devices are very promising. Due to their small dimensions they can offer an increased sensing surface, strong binding properties, faster responses, and can boosted sensitivity (single-molecule detection in some cases) (Fig. 17).

ZnO nanostructures as biosensors have already been used to detect species including hydrogen peroxide, urea, protein, glucose, human immunoglobulin G (IgG), DNA (phosphinothricin acetyltransferase (PAT) gene), phenol, catechol or cholesterol.

Ongoing trials should pave the way to commercialization of implantable, miniature point-of-care biosensors compatible with CMOS/MEMS technology for wireless telemedicine.

Future Perspectives

With almost 9000 publications on ZnO in 2019 (Fig. 18) it is impossible to examine all the potential future applications of ZnO in this chapter.

Fig. 17 Spectra showing the enhanced Raman signal response from a gold-coated nano ZnO plasmonic biosensor relative to a bare glass substrate (for Methyl Blue (MB) functionalization). SPIE* 10533, (105331F-1).

Fig. 18 The number of annual publications vs. year according to a search of the Scopus database for the term “zinc oxide” in the abstract, title or keywords.

Some promising emerging topics are memristors (Simanjuntak *et al.*, 2016), optical waveguides, nanoelectronics, electron scintillators, piezotronics, piezogenerators (Rogers *et al.*, 2012), thermoelectrics (ZnO has the highest thermoelectric figure of merit of all oxides: Ohtaki *et al.*, 2009), photoelectrochemical hydrogen generation (Harinipriya *et al.*, 2012), actuators, phononics, spintronics, infrared plasmonics (Khamh *et al.*, 2018), metamaterials etc. There is also a perspective of what may be termed extreme-condition-electronics based on ZnO's elevated high-field drift velocity (Albrecht *et al.*, 1999) and robustness for high temperature/field/radiation/frequency operation.

Also of note is that a recent Thomson-Reuters study, recorded more publications dedicated to nanostructured ZnO than to carbon nanotubes. This was attributed to the multifunctional nature of ZnO, the ease of fabricating nanostructures by various techniques (including wide-area, low cost chemical growth) and the extremely large family of nanostructure shapes that can be obtained.

Conclusions

The broad range of existing and emerging applications described above testifies to the combination of multifunctionality, market relevance and manufacturability offered by ZnO. If we can extend this to commercially viable bipolar devices in the future (homo-

or hetero-junctions) they may form the basis for brighter/low-threshold excitonic-based UV emitters and fully-integrated transparent/flexible all-oxide electronics offering novel functionality combinations such as biocompatibility, flexibility and transparency, combined with an intrinsic robustness to high temperature/power/field/radiation/frequency operation (Nozawa, 2007).

Varistors in Surge Protection

The occurrence of the transient events in the power, telecommunication, and data systems is unavoidable. The sources of such events are switching maneuvers as well as direct or indirect lightning strikes on the system infrastructure. Lightning and switching generated transient events (surges), typically lasting in the range of tens of μs to tens of ms may cause severe damage to the power system equipment, degrade wiring insulation, and destroy electronic devices.

Transient surge protectors, commonly known as Surge Arresters in the medium- (MV) and high-voltage (HV) systems, and Surge Protective Devices (SPDs) in the low-voltage (LV) systems, attempts to limit the overvoltage afflicting the electric device or power subsystem below a safe threshold, by diverting the surge current to the earthing system and largely absorbing its energy. A large portion of modern surge protective devices is based on Metal Oxide Varistors (MOVs), which exhibit highly nonlinear IV (current-voltage) characteristics conducting large currents in case of applied voltages higher than their breakdown voltage. In the contemporary surge protection industry, by MOVs, we are mainly referring to the Zinc Oxide (ZnO) varistors, as it is the case here as well.

Usually certain additional components (see Fig. 1), to the main voltage-limiting component (MOV), are necessary to guarantee their safe operation in the case of failures. In-series fuse operates and safely disconnect the MOV from the main power supply if the later one goes to the unexpected short-circuit failure. While the MOV diverts and absorbs the surge currents, an in-series thermal disconnect assembly prevents the undesirable and uncontrollable failure of the nonlinear element if the later one exhibits progressive temperature increase above the sustainable limit. The progressive temperature increase and so-called thermal runaway of the varistors usually occurs in the case of the temporary overvoltages (TOVs), and due to the aging (degradation) process of the varistors.

Temporary overvoltages are system voltages typically higher than the breakdown (nominal) voltage of the varistor, and lower than surge generated voltage spikes. Nominal or breakdown voltage of the modern varistors is usually a voltage forcing 1 mA ($\sim 10^{-5} \text{ A/cm}^2$) of current through the varistor. Temporary overvoltages can last significantly longer (in the range of seconds to hours) than lightning-induced surges.

Zinc Oxide Varistors

The groundwork of zinc oxide varistors was made in 1968 and later presented in Matsouka (1971), where the author describes zinc oxide ceramics in detail, production of it, temperature characteristics, nonlinear properties, etc. Shortly after, the zinc oxide varistors were commercialized and have become the most dominant surge protection element in the industry (Eda, 1989; Levinson, 1986; Gupta, 1990; He, 2019). Today, varistors are available in a very wide range of operating voltages, sizes, current conduction magnitudes, and energy handling capabilities. They are mainly used for protection of the electronic circuit, power, and data systems against destructive overvoltages induced by lightning strikes and switching operations, as already discussed in the previous section.

Conventional methods for the production of the ZnO based varistors are well-established with more than 40 years of industrial manufacturing. Zinc oxide varistor is a type of semiconductor ceramics produced mainly by Liquid Phase Sintering (LPS) (German et al., 2009; Arefin et al., 2009; Matsouka, 1971; Levinson, 1986; Clarke, 1999) of the ZnO powder and other metal oxide additives such as bismuth oxide (Bi_2O_3), antimony oxide (Sb_2O_3), cobalt oxide (CoO), chrome oxide (Cr_2O_3), aluminum oxide (Al_2O_3), and others, hence the name Metal Oxide Varistor (MOV). Such manufacturing methods are well defined in Matsouka (1971), May (1977), Begum (1996), and McArdle (1995). Each of the additives has its role, from the grain-growth retardants/enhancers to the nonlinearity inducers, in the forming of the varistor ceramics and its properties.

Post-sintering varistor ceramic results in a polycrystalline matrix of the doped ZnO grains surrounded by the inter-granular layer. Inter-granular layer mainly consists of the bismuth-rich phase partially, where there is no grain-to-grain boundary formed, coating the ZnO grains throughout the microstructure and forming an interconnected mesh. During the sintering process, the nonlinear IV characteristic is created on the grain-to-grain (GB) boundaries overall producing the nonlinear behavior of the

Fig. 1 Metal-Oxide Varistor (MOV) connected in series with additional components ensuring safe failure mode of surge protective devices.

Fig. 2 Left: Different types of varistor disks used in the surge protection industry. Right: Typical varistor microstructure with the distinct regions. Grain boundary (GB) facilitates the nonlinear behavior of the varistor. ZnO grains act as a low ohmic resistance with specific resistances in the range of $0.1 - 1 \Omega \text{ cm}$. The intergranular layer acts as an insulating layer up to its melting temperature ($800\text{--}900^\circ\text{C}$) above which it melts and creates a highly conductive region. Typical grain sizes of modern varistors are in the range of $5 - 20 \mu\text{m}$. Reproduced from Matsouka, M., 1971. Non-ohmic properties of zinc oxide ceramics. Japanese Journal of Applied Physics. 10, 736–746.

varistor, i.e., voltage-dependent resistor. While the GB exhibits a nonlinear (nonohmic) behavior, the ZnO grains itself have ohmic properties with specific resistances ρ_g in the range of $0.1 - 1 \Omega \text{ cm}$ (Levinson, 1986).

Different types and shapes of the varistors are shown in Fig. 2. Varistor disks can be as well coated with epoxy resin to strengthen their surface dielectric performance. The typical polycrystalline microstructure of the varistors is also shown in Fig. 2, where distinct areas are distinguishable. Details on the varistor microstructure have been discussed extensively elsewhere (Daneu *et al.*, 2011; Matsouka, 1971; He, 2019). Typical average grain sizes of modern varistors are in the range of $5 - 20 \mu\text{m}$. Varistors with different (from nanometers to micrometers) average grain sizes are also produced (Li *et al.*, 2006; Tan *et al.*, 2009). The grain size mainly decides the varistor thickness for desired breakdown voltage and energy handling properties, thus also affecting the residual voltage and surge current rating.

The conductivity of the grains is controlled by different metal oxide additives (Meng *et al.*, 2017), and a very refined production process is required to obtain the optimal grain conductivity and GB characteristics relations. The intergranular layer, consisting mainly from the bismuth-rich phase, acts as an insulating layer up to its melting temperature ($800\text{--}900^\circ\text{C}$) above which it can melt and create a highly conductive region (Matsouka, 1971). The EDS (Energy-dispersive X-ray spectroscopy) of a typical MOV microstructure is shown in Fig. 3, where the chemical content of the microstructure phases (ZnO grain, Bi-rich and spinel phase) is given quantitatively.

In normal (constant leakage current) operation the temperature of the varistor mainly stays in the range of environment temperature. During surge absorbing transients or short duration TOVs a varistor will reach the temperatures up to $100\text{--}150^\circ\text{C}$ and safely cool down to environment temperature after the surge event. However, if the maximum absorbing energy of the varistor is exceeded, the temperatures inside the microstructure may reach melting temperature of Bi-rich phase progressively leading to the varistor failure.

The grain boundary (GB) facilitating the nonlinear behavior of the varistor is a physical junction of two ZnO grains. During the sintering process, the doping of the pure ZnO powder occurs simultaneously with the grain-growth process. This leads to the creation of the electrically active grain-to-grain junction with a diode-like behavior. The physical process governing the GB electrical characteristics have been discussed and researched extensively. However, up to this date, there is no single physical description covering all aspects of the GB characteristics (Eda, 1978, 1989; Clarke, 1999). Most accepted model is based on a double Schottky barrier (He, 2019), nonetheless failing to explain all electrical properties of the GB and all the macroscopic electrothermal performances of varistors.

As can be seen from Fig. 2, the microstructure of the varistor is highly nonuniform having both geometrical as well as electrical nonuniformities. Grains have different sizes, usually scattered in log-normal distribution, and different ohmic resistances while the grain boundaries have different breakdown voltages, different nonlinearities, and even remain purely ohmic. Nonetheless, macroscopically the varistor behaves like an electric device defined with its highly nonlinear IV characteristic.

Electrically the ZnO varistor is function-wise equivalent to the back-to-back Zener diode. The elementary model of the varistor, based on microstructure properties, can be described with the equivalent circuit shown in Fig. 4. The equivalent circuit consists of four components: (1) series resistance R_g depicting (substituting) the cumulative resistance of the varistor's grains, (2) parallel parasitic capacitance C_p depicting the cumulative GBs parasitic capacitance, (3) parallel parasitic resistance R_p depicting the cumulative GBs leakage resistance, and (4) series nonlinear voltage-dependent resistor $R(V)$, depicting the cumulative effect of the GBs. Further, the voltage-dependent resistor can be described (modeled) with the voltage-dependent current source having IV characteristic ($I(V) = I_n(V/V_n)^\alpha$) approximating the electrical behavior of GBs. Parameters V_n and I_n are varistor's breakdown voltage and current, respectively.

In practice, the V_n is evaluated at 1 mA (or $\sim 5 \times 10^{-5} \text{ A/cm}^2$) conduction current which is the typical breakdown (nominal or knee) current of the modern varistors. Parameter α defines a degree of the nonlinearity (amount of the current change in respect to the voltage change) of the varistor. In the first decades of the ZnO varistor development, the manufacturers were trying to achieve

Fig. 3 Energy-dispersive X-ray spectroscopy (EDS) analysis of the microstructure chemical content of typical commercial varistor: (a) spinel (mainly $\text{Zn}_7\text{Sb}_2\text{O}_{12}$), (b) ZnO grain (mainly ZnO), and (c) Bi-rich phase (mainly Bi_2O_3). Adapted from Barrado, C., Leite, E., Bueno, P., Longo, E., Varela, J., 2004. Thermal conductivity features of ZnO-based varistors using the laser-pulse method. *Materials Science and Engineering: A*, 371, 377–381, doi:[10.1016/j.msea.2003.09.069](https://doi.org/10.1016/j.msea.2003.09.069).

high α values, approximating the ideal varistor, however, it was quickly realized that varistors with lower α values exhibit a more stable performance under TOV stress. For modern varistors, the value of α ranges from 30 to 50. Typical values of R_g , R_p , and C_p are in the range of 10 – 500 m Ω , 10 – 50 M Ω , and 1 – 100 nF, respectively. Evidently, the values of the beforementioned parameters would depend on the varistor micro- and macro-scale geometry.

In a continuous operating mode, a varistor is stressed with the voltage below its characteristic breakdown voltage, conducting currents in the range of μA . Such current is very often described, as the leakage current. When the applied voltage exceeds the

Fig. 4 A basic macroscopic model of the varistor describing both linear and nonlinear (voltage-dependent) microscopic properties. The voltage-dependent resistance can be described as voltage-dependent current source having empirical expression approximating the overall GBs IV characteristic.

Fig. 5 JE characteristic of a typical ZnO varistor (blue-circle line). JE characteristic of a varistor's model shown in Fig. 4 (red-square line) – the characteristic is shifted in a vertical direction so as to clarify the representation.

breakdown voltage, what is the case during TOVs and surge events, the varistor becomes highly conductive capable of conducting large transient currents in the range of A to kA having very small voltage drop increase (high nonlinearity). When the voltage returns to the operating (system) level, the varistor returns to its high-resistance state again conducting leakage current.

In the case of very high overvoltages, the varistor is fully conductive and the GBs effect is minuscule, therefore the voltage drop across the varistor is mainly decided by the ohmic resistance of the varistor grains. Ohmic-capacitive leakage and ohmic grain resistances cause the linearization of the varistor characteristics at very low and very high currents. The intermediate region (above the breakdown voltage and below the high current region) is governed by the GBs, thus the nonlinear characteristics. Such behavior is represented by the varistor IV characteristic shown in Fig. 5 (red), which is also the characteristic of the varistor equivalent circuit from Fig. 4.

Conclusively, a varistor's IV characteristics can be divided into three distinct regions as follows: Region 1: pre-breakdown (leakage current) region controlled by R_p and C_p , Region 2: highly nonlinear breakdown region controlled by $I(V)$, and Region 3: up-turn region controlled mainly by R_g . However, the effect of all beforementioned processes, coupled with their scattered values, interpolates throughout the whole IV range obscuring the transition between dominant effects in the Regions 1, 2, and 3. This leads to the smoother IV characteristic of the actual varistor shown in Fig. 5 (blue). Nonlinearity degree parameter α can be calculated by the following expression

$$\alpha = \frac{\log(I_2) - \log(I_1)}{\log(V_2) - \log(V_1)}, \quad (1)$$

where (I_1, V_1) and (I_2, V_2) are set of current/voltage values (points) in the breakdown region (Matsouka, 1971; Eda, 1989; Levinson, 1986; Clarke, 1999; He, 2019). Most commonly the α is measured/evaluated by using a constant current source, where I_1 and I_2 values are set to 1 and 10 mA, respectively. For both currents the voltage drops V_1 and V_2 are read-out and by using Eq. (1) the α is calculated.

Due to the high nonlinearity and thus very large current change with respect to very small voltage change, the varistors' characteristics are often given in log-log or log-linear scale with the current on the x-axis. If the current change is given by some factor x , i.e. $I_2/I_1 = x$ then, the voltage change in the nonlinear region can be simply calculated as $V_2/V_1 = x^{1/\alpha}$.

Fig. 6 Pinhole (puncture) failure of the varistor. This kind of failure results in the creation of the through-hole in the varistor body with highly conductive deposits on the hole walls. Pinhole is usually around 0.5–1 mm in diameter. Adapted from Vojta, A., Clarke, D., 1997. Microstructural origin of current localization and puncture failure in varistor ceramics. *Journal of Applied Physics*. 81, 985–993. doi:10.1063/1.364226.

Nonuniformity of Varistors Microstructure

Due to the grain microstructured nature of zinc oxide ceramics, distribution of additives and production process, the non-uniformity became an inherited property of any ZnO varistor (Modine, 2001). First to explore non-uniformity phenomena were Mizukoshi *et al.* (1983). Following their results (Eda, 1984) discussed puncture failure of ZnO varistors due to current localization caused by varistor non-uniformity. Structural non-uniformity of ZnO varistor was proven to be a key factor causing current localization inside varistor ceramics. Authors in Greuter and Blatter (1990) have experimentally shown current localization at microstructure by means of electroluminescence (Pike *et al.*, 1985). The fact that origins of “electrical” non-uniformity of ZnO varistor are not only caused by structural non-uniformity such as grains size distribution has been proven by Tao *et al.* (1987). The authors have experimentally shown that every single micro-junction in varistor ceramics presents its own electrical characteristic.

Therefore, electric current distribution inside the ZnO varistor is determined by structural non-uniformity, distribution of electrical properties of single micro-junctions and, as shown in Mizukoshi *et al.* (1983) and He and Hu (2007) as well as in this work, on the applied voltage across the varistor.

Current localization, as underlying phenomena of the pinhole failure, was further explored in Vojta and Clarke (1997), where the varistor microstructure was modeled as a uniform network of nonlinear resistors. The physical process of the pinhole failure would be discussed later, while here a quick introduction is given. Current localization leads to extensive heating in the localized current path melting it and eventually, due to the high temperatures, evaporating the material from it. After the varistor’s destruction and disconnection from the mains (in-series fuse or thermal disconnecter operates) a pinhole mode failure of the varistor manifests as an approximately 1 mm wide through-hole in the varistor body. The inner wall of the pinhole mainly consists of melted Bi-rich phase and ZnO (MOV) grains having very low ohmic resistance, thus effectively short-circuiting the varistor. The image of the cross-section of the pinhole failure mode is shown in Fig. 6.

To more explicitly represent the nonuniformity of the varistor polycrystalline structure authors in Bartkowiak *et al.* (1996) proposed a Voronoi network as a basis of composing the nonuniformly connected grid of nonlinear resistors, as shown in Fig. 7. Comparing the Voronoi network geometry and SEM (Scanning Electron Microscope) imaging of ZnO crystals as shown in Clarke (1999) and Chen *et al.* (2002), one can easily justify the use of such an approach. Authors in Bartkowiak *et al.* (1996) have used the Voronoi network as a basis for constructing a non-uniformly connected network of nonlinear resistors which, as also shown in Vojta and Clarke (1997), results in solving a set of current conservation equations by means of circuit analysis. By assigning different (distributed) threshold voltages and nonlinearity coefficients to the nonlinear resistors in the Voronoi generated network the authors in Bartkowiak *et al.* (1996) managed to combine both structural and “electrical” non-uniformity of varistor ceramics.

After this work, several contributions have been reported (Bartkowiak *et al.*, 2001; Chen *et al.*, 2002; He *et al.*, 2005; He and Hu, 2007; Long *et al.*, 2010) using numerical models with Voronoi network for analysis of ZnO varistor electrical characteristics. Current non-uniformity modeling inside ZnO varistor using Voronoi network presented by He and Hu (2007) showed current localization phenomena dependency on the applied voltage across the varistor. The results indicated that localization reaches its maximum at TOV (temporary overvoltage) region of voltage magnitudes.

Modeling of ZnO varistor with FEM (Finite Element Method) was previously reported by Lengauer *et al.* (2000). They performed FEM analysis to calculate mechanical stresses inside a ZnO disk where the disk ceramics was represented as a homogeneous solid cylinder. Authors in Frigura-Iliasa *et al.* (2010) presented an FEM model for calculation of heat losses in the varistor by assuming varistor ceramics as a homogeneous solid (as in Lengauer *et al.* (2000)). Authors in Bavelis *et al.* (2014) proposed a 3D FEM model for current distribution analysis inside a ZnO varistor by representing the grain-structured geometry with a 3D Voronoi network. A drawback of this work is that the FEM model was used only to calculate a conductance matrix of

Fig. 7 Voronoi network approach in modeling of the varistors microstructure proposed by Bartkowiak *et al.* Simulation results in creating a nonuniformly connected grid of the (nonlinear) resistors of which the properties are calculated from the Voronoi network (edges lengths d_{ij}) and some empirical expressions depicting I/V characteristics behavior. N is the total number of resistors in the network and R_g ohmic grain resistance. Once the current through the network resistors R_{ij} are calculated, these values can be then represented by color code, back on Voronoi network grains, which is usually done in the literature. Reproduced from Bartkowiak, M., Mahan, G.D., Modine, F.A., *et al.*, 1996. Voronoi network model of ZnO varistors with different types of grainboundaries. *Journal of Applied Physics*. 80, 6516–6522.

ZnO grains, which was later used in a 3D nonlinear resistor network. Therefore, the presented model still results in a circuit analysis without solving for the electric field in the modeled geometry.

Energy absorption (handling) capability (EAC) of the varistors (MOVs) (Matsouka, 1971; Clarke, 1999; Eda, 1989; He, 2019) is a pivotal parameter influencing their performances as well as failure characteristics. In the early 1980s, it was realized that the EAC of the varistor fundamentally depends on its microstructure (non-) uniformity as well as stress conditions (Mizukoshi *et al.*, 1983; Kan *et al.*, 1983). In Mizukoshi *et al.* (1983) and Kan *et al.* (1983), authors have experimentally obtained the relations between varistor's uniformity, TOVs, and EACs, elucidating their quantitative cross-dependence.

To advance the understanding of the EACs, Eda (1984) has proposed a varistor model capable of solving and predicting electrothermal behavior of the varistors under specified stresses and microstructure nonuniformities. The presented model was based on the depiction of a varistor as a composite of multiple homogeneous cylinders electrically described with the same current density-electric field (JE) characteristics having different breakdown voltages. Irrespectively of the model geometrical simplicity, the obtained results had agreed well with the experimental data demonstrating severe current localization and Joule heating in the varistor body consequently leading to the pinhole (puncture) failure of the varistor under TOV conditions.

Additional work in this direction was done by Bartkowiak *et al.* (1999) presenting a model of the varistor which includes simulations of the mechanical stresses due to the rapid and nonuniform heating. This approach covered two modes of varistor failures, namely, cracking and puncture.

Cracking of the varistor is, alongside the puncture failure, a second most common mode of the varistor failure. It typically occurs when a varistor is subjected to extremely short pulses (in the range of 10 microseconds) having much larger current densities and voltage magnitudes than those conducted in the case of pinhole failure. Such stressing of the varistor causes a rapid highly nonuniform heat-related expansion of the material (mechanical shock wave) eventually resulting in the cracking of the varistor body. Fig. 8 shows the cracking mode failure, where distinct regions are observable; crack is parallel with the stressing electrical field (current conduction) and propagates through the whole varistor body. Inner walls of the crack show a violent fracture of the material without melted phase, close to the fracture a recrystallization process can also occur (He, 2019).

Fig. 9 illustrates the typical modes of the MOVs failures, as looked from above (in the voltage-applied direction). It also indicates the stressing conditions which are causing the specific failure modes. However, while a large percentage of the observed failure modes, as a function of the stressing condition, will follow the observed characteristic shown in Fig. 9, the non-disregardable uncertainty still remains on which failure will eventually occur. It is worth mentioning that a cracking failure usually does not result in the short-circuiting of the MOV, nonetheless a combination of pinhole and cracking failure may as well occur.

Previous reports (Mizukoshi *et al.*, 1983; Kan *et al.*, 1983; Eda, 1984; Ringler *et al.*, 1997; Bartkowiak *et al.*, 1999, 2001; He and Hu, 2007) have unambiguously demonstrated a voltage stress-dependent EACs of the varistors where we can observe a $\sim 50\%$ drop in EAC at TOV conditions versus the EAC levels at surge region. This deduction is also manifested in varistors' time-to-failure characteristics, exhibiting an exponential decrease for overvoltages in the range of 1.1–1.6 times the nominal voltage (Kan *et al.*, 1983; Khanmiri *et al.*, 2017). Recent large-scale experimental findings reported by Tuzek and Hinrichsen (2014) have endorsed and uphold previous experimental and simulation data.

Fig. 10 shows the varistors energy absorption capability as a function of the current densities, where a substantial increase in the EAC value at higher densities is visible. It is worth mentioning that different current waveforms are used when measuring EACs at TOV and surge regions. For TOV current magnitudes an AC source is used, where for surge current magnitudes the surge generators are used (IEC, 2011).

Fig. 8 Imaging of the crack cross-section within the varistor body. While here the crack resembles the pinhole failure (see Fig. 6), the width (length) of it extends throughout a much larger portion of the varistor body. Adapted from He, J., 2019. Metal Oxide Varistors: From Microstructure to Macro-Characteristics. Wiley-VCH Verlag GmbH and Co. KGaA. doi:10.1002/9783527684038.

Indubitably, as previously noted, such an undesired drop in a varistor's EACs at TOV region arises from the severe current localization in the microstructure, where the effective current-carrying (i.e. energy-absorbing) volume decreases dramatically. Quantitative evaluation of the effective volume decrease is still mainly vague; Vojta (Vojta and Clarke, 1997; Vojta *et al.*, 1996), based on simulation, sets the lowest effective volume (at highest localization) to $\sim 10\%$ and the recent IEEE C62.55–2017 (IEEE, 2017) guideline set this level to $\sim 2\%$. Due to the large scale presence of varistors in the surge protection industry, and the importance of the contemporary protection of modern power systems, the varistors nonuniformity and current localization phenomena are still the subjects of up-to-date research (Huang *et al.*, 2019; He *et al.*, 2018; Jianying *et al.*, 2018; He, 2019; Meng *et al.*, 2019; Topcagic *et al.*, 2019).

Modeling of the Varistor Microstructure

Recent research reported in Topcagic *et al.* (2018, 2019) has advanced modeling of the electrothermal phenomena within the varistor microstructure by the combination of a Voronoi network and a Finite Element Method (FEM). By employing FEM analysis authors have modeled varistor polycrystalline microstructure in 2D as well in 3D space. It is worth mentioning that, when modeling electrothermal characteristics of the MOVs former published research (Vojta and Clarke, 1997; Bartkowiak *et al.*, 1996; Bartkowiak *et al.*, 2001; Chen *et al.*, 2002; He *et al.*, 2005; He and Hu, 2007) have mainly used a 2D Voronoi network, which can be only justified by comparing it to the polished surface of the MOV (see Fig. 2). A real MOV microstructure excludes symmetries in any direction, thus a 3D Voronoi network should be used as shown in Bavelis *et al.* (2014). Nonetheless, a 3D Voronoi network fails to represent the actual sphericities of the MOV microstructure, thus the more truthful approach is to use the grain-growth model (Quey, 2019).

The unpolished SEM imaging of the typical commercial MOV surface is shown in Fig. 11. Comparing the grain structure shown in Figs 11 and 7 with those shown in Fig. 2, the difference is clearly observable justifying the usage of the grain-growth model instead of the 2D Voronoi network.

By modeling a fraction of the varistor microstructure the electrothermal behavior of the microstructure can be explored. The voltage-dependent current localization inside the modeled microstructure, for different overvoltage stresses, is shown in Fig. 12. From Fig. 12, we can also observe the modeled 3D microstructure by grain-growth algorithm presented in Quey (2019). At values of applied overvoltage stress corresponding to the leakage region, the current distribution is slightly non-uniform. When the applied overvoltage reaches a TOV range the maximum localization occurs generating the dominant percolation path. At overvoltages going from TOV to surge range, the current distributes across the whole microstructure leading to the nearly uniform distribution. The current distribution as shown in Fig. 12(c) suggests that the creation of the main percolation path, which would eventually lead to the pinhole failure, occurs on a single-grain width.

Quantitative evaluation of the current localization, indicating microstructure behavior (performances), can be described by the participation factor formerly proposed in Vojta and Clarke (1997) and described in Topcagic *et al.* (2018, 2019). The participation ratio represents the amount of microstructure volume carrying the majority of the current at a given voltage/current load. It was observed that the participation ratio is highly stress-dependent and for the microstructure as shown in Fig. 12, the participation ratio is shown in Fig. 13, indicating the occurrence of maximum localization at overvoltages ratio equal to $\sim 1.1(E/E_n \approx 1.1)$. At

Fig. 9 Above: Illustration of the destruction modes of the varistors, looking from above onto the electrode surface with destruction modes as a function of the stressing conditions according to Eda and He. Below: Images of several typical failure modes: (a) cracking at the edge, (b) pinhole (puncturing) through the side, (c) fracturing at the inner region, and (d) fracturing and puncturing under impulse currents. Adapted from Eda, K., 1984. Destruction mechanism of ZnO varistors due to high currents. *Journal of Applied Physics*. 56, 2948–2955. He, J., 2019. Metal Oxide Varistors: From Microstructure to Macro-Characteristics. Wiley-VCH Verlag GmbH and Co. KGaA. doi:10.1002/9783527684038. Meng, P., Zhao, X., Yang, X., *et al.*, 2019. Breakdown phenomenon of ZnO varistors caused by non-uniform distribution of internal pores. *Journal of the European Ceramic Society*. 39, 4824–4830, doi:10.1016/j.jeurceramsoc.2019.06.043.

overvoltages less than 0.75, corresponding to the modeled varistor's leakage region, the participation factor is $> 80\%$ indicating slight non-uniformity, and at overvoltage ratio of 1.05 – 1.2 the participation factor drops down to only 4%. With overvoltage increase, the participation factor tends to saturation (more than 80%). The obtained results are in good agreement with previous reports (Vojta and Clarke, 1997; Topcagic *et al.*, 2018), however predicting more severe conditions, as those deduced experimentally (IEEE, 2017).

By means of the 3D model, the dynamic electrothermal behavior of the varistors microstructure can be evaluated by calculating EACs, under specified current stress. The calculation of EAC, as shown in Topcagic *et al.* (2019), has been performed by applying different overvoltage ratios (1.1–2.0) to the modeled geometry and evaluating absorbed energy up to the time at which thermal runaway starts. The results are shown in Fig. 13 indicating lowest EAC values ($\sim 500 \text{ J/cm}^3$) at TOV range and highest values ($\sim 2300 \text{ J/cm}^3$) at surge region. Clearly, such dependency of the EAC is due to the current localization within the MOV microstructure and effective volume decrease elucidated by the participation factor p . The obtained numerical results are in good agreement with experimental data previously reported in Ringer *et al.* (1997) and Khanmiri *et al.* (2017) (see Fig. 10).

As previously noted, the nonuniform current distribution raises purely from the microstructure nonuniformity without considering other factors such as difference in GBs breakdown voltages, low- α or ohmic GBs (Bartkowiak *et al.*, 2001), and the presence of pores. However, latest research (Meng *et al.*, 2019) has indicated a more important role of pores in the current conduction. Authors in Meng *et al.* (2019) have analyzed the internal structure of ZnO varistors with X-ray micro-CT technology and showed that the porosity and pore volume at the radial edge of the varistor disk is considerably higher than at other varistor areas. This observation and measurements for selected varistor specimen is shown in Fig. 14.

Fig. 10 Energy absorption capability as a function of the current density: (a) Experimental results reported in Ringler *et al.*, and (b) Large-scale experimental results reported in Tuczek and Hinrichsen. Reproduced from Ringler, K.G., Kirkby, P., Erven, C.C., Lat, M.V., Malkiewicz, T.A., 1997. The energy absorption capability and time-to-failure of varistors used in station-class metal-oxide surge arresters. IEEE Transactions on Power Delivery. 12, 203–212, doi:10.1109/61.568242. Tuczek, M.N., Hinrichsen, V., 2014. Recent experimental findings on the single and multi-impulse energy handling capability of metal-oxide varistors for use in high-voltage surge arresters. IEEE Transactions on Power Delivery. 29, 2197–2205, doi:10.1109/TPWRD.2013.2283911.

The influence of pores on current distribution and energy handling capability of MOVs may be of significant importance since, as experimentally shown in Meng *et al.* (2019) as well empirically deduced and recognized previously (Andoh *et al.*, 2000), the breakdown phenomenon usually occurs near the outer edge of the varistors. Authors in Meng *et al.* (2019) have used 2D Voronoi network simulations in order to study the influence of pore defect on the characteristics of the microstructure. Simulations have indicated increased voltage gradient along the simulated microstructure as the proportion of pores increased. In contrast with the increased pores proportion, the leakage current slightly decreased. Details and additional discussions are provided in Meng *et al.* (2019), while herein, we can emphasize the importance of microstructure modeling by means of electrical circuits based on nonuniform structures (Voronoi network, grain-growth (Quey, 2019; Topcagic *et al.*, 2019)), enabling important insight in the electrical behavior of the varistors microstructures.

Alongside pores it was shown by Huang *et al.* (2019) that peripheral areas (edges) of the varistor disks tend to have, even in the case of same grain sizes compared to the inner areas of the MOV disk, different GB properties, overall contributing to the slightly different IV characteristic as indicated in Fig. 15. Such difference, where we can observe down-shifted JE characteristics of the outer section of MOV disk having lower breakdown field, will cause current localization in that area producing nonuniform heat dissipation and eventually leading to the varistor failure.

Voronoi network simulations have also been proven as an effective tool in modeling of the nonlinear composite dielectrics based on ZnO micro-varistors. Nonlinear dielectrics are used (useful) for the electric stress mitigation and electric field grading in electrical insulation applications such as corona protection in rotating machines, high voltage cable joints, and cable terminations (Christen *et al.*, 2010; Donzel *et al.*, 2011; Rivenc and Lebey, 1999; Weida *et al.*, 2011; Qi *et al.*, 2004). Fig. 16 shows an illustration

of the ZnO micro-varistor based nonlinear dielectric, where a percentage of the micro-varistors is of crucial significance in optimizing and developing such materials. In that light authors in Yang *et al.* (2016a,b) discuss the percolation process and the properties of the composite dielectric by means of Voronoi network simulations. It is worth mentioning the extended possibilities of such simulations by means of 3D approach presented here and in details in Topcagic *et al.* (2019). FEM model, alongside 3D capability and proposed GB model, easily enables the electrothermal coupling, which could be used in order to investigate heat initiated degradation of composite nonlinear dielectrics.

Failure Mechanisms of the Varistors

It is well-established fact that the varistors failures, namely, pinhole and cracking can be attributed to the varistor structural and electrical nonuniformity. Pinhole failure usually occurs at TOV conditions while cracking occurs at surge currents. The mechanisms of the pinhole failure have been explored by means of simulations by Bartkowiak *et al.* (1999), Meng *et al.* (2019), He *et al.* (2005), and Topcagic *et al.* (2018, 2019) as well as others. In general, the pinhole occurs due to the extensive Joule heating at the localized current paths. This can be observed in Fig. 17, where for a given TOV load (see Fig. 18) the current conduction and localization within microstructure produce severe heat accumulation and temperature rise in the main percolation path. Such condition progressively leads to the creation of hot-spot (HT), (see Fig. 18) with temperatures above 400–500°C causing permanent varistor degradation with increased current (up to time t_f). Continuing current conduction, above the time t_f , leads to further hot-spot temperature increase eventually exceeding the melting temperature ($\sim 830^\circ\text{C}$) of intergranular Bi-rich phase. During the melting process of the Bi-rich phase, the highly conductive layer, surrounding the individual ZnO grains, is created, effectively bypassing the GBs. This is manifested in the drastic current increase clearly elucidated in the Fig. 18, which ultimately leads to the complete melting of the percolation path, i.e., MOV's pinhole failure. Evidence of this process is reported in He *et al.* (2018), where authors had observed a larger amount of the Bi-rich phase, with respect to the un-stressed MOV, in the areas of the MOV body close to the pinhole.

Experimental evidence of the Joule heating in the varistor microstructure during TOV load is shown in Fig. 19, where localization paths and extensive nonuniform Joule heating is visible. Such a load would eventually lead to the pinhole failure of the varistor. It is worth mentioning that except for the total melting of Bi-rich layer, the pinhole failure at lower conduction currents values may be initiated by the degradation of the GBs themselves, which gradually degrade by decreasing their breakdown voltages. This mechanism of degradation is contributed by migration of charge carriers within the GB depletion layer (He, 2019).

Fig. 12 Distribution of the current density $\log_{10}(|\vec{J}|)$ (in logarithmic scale) at different overvoltage ratios, which corresponds to applied electric field E divided by nominal electric field yielding $\sim 5 \times 10^{-5}$ A/cm² conduction, E/E_n as follows: (a) 0.28, (b) 1.09, (c) 1.18, (d) 1.50, (e) 1.90, and (f) 2.50, where the knee (breakdown) electrical field of the 3D model was approximately 117.0 V/mm. The creation of percolation (preferable) current paths as well as current distribution with respect to overvoltage ratio is clearly visible. Some sections of microstructure are hidden so as to show the current distribution inside the model.

Fig. 13 Voltage-dependent grain participation factor p in respect to the applied overvoltage E/E_n . The participation ratio reaches the lowest value of $\sim 3.7\%$ at the overvoltage level equal to ~ 1.1 . Simulated voltage-dependent energy absorption capability EAC with respect to the applied overvoltage. The lowest EAC values at TOV range are in the range of $300 - 400 \text{ J/cm}^3$.

Fig. 14 The proportion of pores per specimen and 3D structure and distribution of internal pores within the region of edge-1 and inner-2. Adapted from Meng, P., Zhao, X., Yang, X. *et al.*, 2019. Breakdown phenomenon of ZnO varistors caused by non-uniform distribution of internal pores. *Journal of the European Ceramic Society*. 39, 4824–4830, doi:10.1016/j.jeurceramsoc.2019.06.043.

As possible underlying mechanism of cracking phenomena, which can also be produced by rapid heating leading to the nonuniform mechanical stress inside the microstructure as discussed by Bartkowiak *et al.* (1999) and others, however, the cracking phenomenon cannot be directly related to the current localization as it is the case in the pinhole failure mode. The reason for this is the fact that cracking failure mostly occurs during surges, which generate large overvoltages (> 2.0) on the varistors and according to the participation factor (see Fig. 13) a majority of varistor volume should participate in surge current conduction, thus excluding severe current localization.

To answer some aspects of this type of failure, authors in Meng *et al.* (2019) provide the discussion on the effect of the pores as the initiator of the cracking failure. Authors state that “the pores are insulating under low electric fields and the current through the pores is almost zero. Hence, the voltage gradient at the edge region is higher than that elsewhere.” The effects of the pores on the

varistor failures are also discussed in Danzer and Supancic (2018). It could be hypothesized that further increase of the voltage produces ionizing electrical fields on the pores initiating localized arcing. Produced arcing leads to extensive heating and mechanical pressure in the microstructure eventual leading to the cracking failure.

Surface flashovers, as the third most common varistor failure, are contributed by the edge effects on the varistor surface. The majority of the varistors have metalized electrodes, which are either sprayed on the disk surface (arc or plasma spraying) or screen printed (silver paste silk screen followed by thermal treatment). This process leads to the nonuniform edges of the electrodes, which under high overvoltages can produce highly concentrated air-ionizing electrical fields leading to the arcing on the varistors electrode edges. This phenomena is discussed, for example, in Andoh *et al.* (2000) and shown in Fig. 20.

Fig. 17 Distribution of the temperature at different times under ~ 1.1 DC overload (overvoltage ratio). Creation of a pinhole failure. Figures (a) and (c) are showing temperature distribution at times t_s and t_f , respectively. Figures (b) and (d) are showing isotherm contours on times t_s and t_f , respectively. The creation of a pinhole is visible in both figures, where the isothermals clearly indicate the pinhole path. Sections of microstructure are hidden so as to show the temperature distribution within it.

Practical Guidelines

The decrease of the EACs of the varistors, due to the stress-dependent current localization, quantified by the participation factor (see Fig. 13), is observable during the varistor energy rating measurements. Typically, varistor's energy rating is measured by stressing it with surge currents, commonly with 8/20 or 10/350 wave according to IEC (2011), which is produced by two types of surge generators, namely, crowbar- and discharge-type generator (Schon, 2013). It can be observed that for the same peak (crest) current, the discharge-type generators impose higher stresses, i.e., varistors could not withstand the same current rating deduced (measured) on crowbar-type generators; experimentally determined impulse current ratings may differ up to 40% depending on generator type and design. The reason for this is very simple; during the wave tail of the surge current, generated by discharge-type generators, the MOV is exposed to overvoltage conditions (similar to TOV region) for long times (in several milliseconds range) determined by the over-damping impulse current circuit, whereas for crowbar-type generators the current wave-tail is interrupted typically within 2 ms. This exposure causes, according to the participation factor, additional highly-localized Joule heating on already preheated MOV, eventually leading to the puncture failure. Assuming the adiabatic heating in TOV region, the hot-spot temperature, thus the time-of-failure (see Fig. 18), can be roughly predicted applying the following expression,

$$\Delta T = \int \frac{I(V, t)V(t)}{c_p m_v \rho(V(t)/V_n)} dt, \quad (2)$$

where m_v and c_p are varistor volume and heat capacity.

The pinhole failure behavior of the MOVs under TOVs discussed in the sections above is well-recognized in the field of surge protection. The thermal runaway characteristics of the MOVs are greatly considered when dimensioning surge protection applications, where the prevention of uncontrolled MOV failure is done by the in-series thermal disconnecter and fuse. Under TOV stress the current flow through varistor vary with time in the following manner; initially, the current exhibits an exponential drop followed by quasi-stable conduction for a time duration which, depending on the magnitude of the overload stress, is followed by a rapid increase in current up to the failure of the varistor. Such behavior resembles a U-shaped current-time curve shown in Fig. 18.

Remarkably, the mathematical representation of a varistor used in the circuit analysis (LT Spice, ATP-EMPT (Dommel, 1986)) tools is still based on a static IV characteristics, thus failing to accurately predict the dynamic behavior of the varistor under TOVs. We should not confuse this with the high-frequency models of the surge arresters presented in IEEE Working Group 3.4.11 (1992), Pinceti and Giannetoni (1999) and Magro *et al.* (2004) commonly used in time-domain transients analysis.

By examining the varistor behavior under TOV conditions, authors in Topcagic *et al.* (2019) provide the dynamic model of the varistors characteristics $IV \rightarrow IVt$, based on empirical expression given as,

$$I(V, t) = \frac{1}{2} I_0(V) \left(k + \left(\frac{q_c}{q_c + q(t)} \right)^{p_q} + \left(\frac{e(t)}{e_c} \right)^{p_e} \right), \quad (3)$$

where I_0 is an initial current deduced from static IV characteristic (as, for example, well-known $I = I_n(V/V_n)^z$ or others) (Topcagic *et al.*, 2018; Khanmiri *et al.*, 2017; Chen *et al.*, 2002; Zitnik *et al.*, 2005; Abdel-Salam *et al.*, 2004), k a fitting parameter in the range of (0.8–1.2) adjusting the ratio of initial and quasi-steady-state current (see Fig. 18), q_c characteristic charge density (4), $q = \frac{1}{m_v} \int I(t) dt$ absorbed charge density, e_c characteristic energy density (4), $e = \frac{1}{m_v} \int I(t)V(t) dt$ absorbed energy density, p_q and p_e fitting powers in the range of (5–6), and m_v an MOV volume. As it is clear from the description, the parameters of the Eq. (3) must be obtained experimentally for every MOV (ceramics) type. Details of the model are discussed in Topcagic *et al.* (2019).

$$\begin{aligned} q_c &= \frac{1}{m_v} \int_0^{t_s} I(t) dt, \quad t_s = t \Big|_{\frac{dI}{dt} \approx 0}, \\ e_c &= \frac{1}{m_v} \int_0^{t_f} V(t) I(t) dt, \quad t_f = t \Big|_{I > 0 \text{ \& } I \approx I_0}. \end{aligned} \quad (4)$$

The aforementioned varistor current (initial drop and thermal runaway) response to the TOV stress, could be as well described as the initial (static) varistor's IV characteristic shift to the right, current ascending, and left, current descending direction (see Fig. 5). This deduction could be used for extending the traditional model (Epcos, 2019; Topcagic *et al.*, 2018) of the static IV characteristic into the time domain, as shown in Eq. (5),

$$\begin{aligned} \log_{10}(V) &= b_1 + b_2 \log_{10}(I/\sigma) + b_3 \exp(-\log_{10}(I/\sigma)) \\ &\quad + b_4 \exp(\log_{10}(I/\sigma)), \\ \sigma &= 1 - \frac{k}{2} + \frac{k}{2} \left(\frac{q_c}{q_c + q(t)} \right)^{p_q} + \left(\frac{e(t)}{e_c} \right)^{p_e}, \end{aligned} \quad (5)$$

where σ is a shifting operator and b_1 – b_4 fitting parameters for initial(static) varistor characteristics. Implementation of the discussed model is presented in detail in Topcagic (2019).

Conclusion

Even though ZnO varistors have been invented in the late 60s and extensively investigated the last four decades, the research on this topic is still noticeably dynamic and active. This work has very briefly covered certain aspects of varistor technology and their microstructural effects on the macroscopic electrical properties. Emphasis has been given to academic and industrial research results associated with recent advancements on varistors performance, failure modes, electromagnetic modeling and surge protection applications allowing for a deeper understanding of their dynamic electrothermal behavior. The presented research results form the basis for accomplishing future challenges:

1. Identification of real-time monitoring techniques of varistors electrical properties in order to be integrated into the next generation of smart surge protective devices in the era of modern power systems.
2. Development of enhanced energy absorption capability varistors so as to withstand long duration electromagnetic pulses with energy content higher than that of lightning strikes covering the cases of solar storms, nuclear electromagnetic pulses and power crossover of neighboring power systems.
3. Development of micro- to nano-varistor materials for smoothing the electric field at cable junctions and limiting the sheath voltages at high power applications.

Fig. 21 Current-dependent participation factor $p(V)$ in respect to the current overload J/J_n , where J_n is a MOV's nominal (breakdown) current density corresponding to the MOV 1 mA nominal current I_n . Simulated current-dependent energy absorption capability EAC.

Appendix

The results of the participation factor p and EACs could be as well rearranged to provide the current-dependent participation factor and EACs, which may be preferential in certain calculations. This is shown in Fig. 21, where we can observe that an EACs, for complete TOV range, can be considered as constant. The difference between Figs. 13 and 21 is a consequence of the fact that a small voltage changes produce extensive current changes, thus the difference in plots' x-axis "width." The calculated EAC results, shown in Fig. 21, even more clearly indicate a good relation with the measurements (Ringler *et al.*, 1997).

Latest Trend of ZnO Multilayer Ceramic Varistors

Eiichi Koga, Yoshiko Higashi, and Michio Matsuoka, Panasonic Co. Ltd., Osaka, Japan

© 2021 Elsevier Inc. All rights reserved.

Introduction

ZnO varistors are used as devices to protect electronic equipment from various overvoltages such as electrostatic discharge (ESD), surges, and lightning (Matsuoka, 1971), (Koga and Sawada, 2009). In recent years, because advanced ICs with miniaturization are easily destroyed by ESD, ZnO multilayer ceramic varistors (MLCVs) are usually employed as protection devices (Koga *et al.*, 2011). The desirable characteristics are high protection performance and high stability so as not to be destroyed by overvoltage such as ESD (Koga *et al.*, 2011). In addition, today there is a need for low-capacitance MLCVs that can be used in high-frequency circuits, such as antennas for wireless communications and high-speed signal interfaces (e.g., HDMI) (Koga *et al.*, 2011). However, it is difficult in conventional MLCVs to achieve both low-capacitance and protection performance (Koga *et al.*, 2012).

In this chapter, the discovery and the mechanism of ZnO varistors are firstly mentioned, and recent issues in practical application are then showed for conventional ZnO varistors with Bi- and Pr additives. To resolve the issues, not only the new varistor material composition but also its MLCVS with a discharge cavity between internal electrodes have been developed in recent years. In addition, as shown in our recent studies, MLCVs with high nonlinearity and ESD stability can be cofired with internal electrodes of base metal. The cutting edge research on ZnO varistors is reported here.

Discovery of ZnO Varistors, and Issues of Conventional Materials

ZnO varistors were invented by Matsuoka *et al.*, and have mass produced since 1971. The discovery was made by the evaluation for bulk bodies of Ag-paste painted ZnO, which were oversintered by the oven runaway – a story that has been handed down as one of the famous examples of serendipity (Higashi and Koga, 2018). As many related papers and books have been published, you can refer to them.

Conventional ZnO varistors are divided into Bi-doped type with oxide additives (Bi, Sb, Co, etc.) and Pr-doped one with Pr oxide etc., invented by Mukae *et al.* (1979); Higashi and Koga (2018). Both types are the same level of high nonohmic ceramics, and their electric resistance considerably decreases with applied voltage. The typical V – I characteristics are shown in Fig. 1. Since the resistance (i.e., voltage) decreases rapidly by several orders of magnitude with increasing an applied voltage, a current bypass is formed with overvoltage by a varistor being connected between a signal line and ground. The voltage at which the resistivity rapidly decreases is defined as varistor voltage (i.e., breakdown voltage), which is the most important index for protection performance. In general, the voltage at a current of 1 mA is expressed as $V_{1\text{mA}}$. As an index for nonlinearity, $\alpha_{10\mu\text{A}} = V_{1\text{mA}}/V_{10\mu\text{A}}$ is often used. The value closer to 1 means that the resistance decreases rapidly by increasing of a current between 10 μA and 1 mA, and the nonlinearity is ideal. To improve the protection performance, it is necessary to lower a voltage in the high current region when overvoltage is applied. As one of the measures, lowering breakdown voltage (i.e., $V_{1\text{mA}}$) is controlled in design of MLCV. The origin of highly nonlinear characteristics around $V_{1\text{mA}}$ is responsible for Schottky barriers between ZnO grains. On the basis of the microstructure, $V_{1\text{mA}}$ is the sum of a voltage ($= V_{\text{gb}}$) per grain boundary along electric field lines between electrodes. Thus, the number of grain boundaries has been reduced by thinning between electrodes or controlling grain sizes (Koga *et al.*, 2012). However, because degradation of nonlinearity and stability occurs with decreasing $V_{1\text{mA}}$ by conventional methods, the control of $V_{1\text{mA}}$ is limited within practical characteristics (Mukae *et al.*, 1979); (Ikoma and Okumura, 1981). The results on lower-voltage

Fig. 1 V – I characteristic of varistors.

Fig. 2 V - I properties of Bi- and Pr- based MLCVs: (a) low-voltage region and (b) after applying ESD.

Table 1 Bulk and grain boundary characteristics of Bi- and Pr-doped ZnO varistors

Material system	$V_{1mA/mm}$ V	$\alpha_{10 \mu A}$ $V_{1mA}/10 \mu A$	V_{gb} V	ϕ eV	Grain size μm
Bi	760	1.18	1.78	1.15	2.7
Pr	540	1.14	1.07	0.64	2.3

limits of Pr- and Bi-based MLCVs are shown in **Fig. 2(a)** and **(b)**. As shown in **Fig. 2(a)**, nonlinearity of Bi-based MLCVs is degraded below V_{1mA} of 12 V. On the other hand, you can see that Pr-based MLCVs have high nonlinearity even down to 8 V. And more, stability against ESD is different between both types as well. Nonlinearity degradation of Bi-based MLCVs is significantly caused by ESD. On the other hand, it is clear that Pr-based MLCVs possess high ESD stability. From the results, the lower-voltage limits are found to be dependent on additives (in grain boundaries) to ZnO.

Development Direction of New Varistor Material

Detailed analysis of Bi- and Pr-doped varistors is conducted to obtain the development direction of the novel material with low-voltage characteristics and strong ESD stability. The difference of characteristics by the additives in the grain boundary compositions gives the development direction of new varistor material. Results obtained are described here.

Characteristics for Grain Boundaries in Bi/Pr-Doped ZnO Varistors

As a comparison of grain boundary characteristics between Bi- and Pr-doped types, nonlinear V - I characteristics ($V_{1mA/mm}$, $\alpha_{10 \mu A}$), average grain size, varistor voltage per grain boundary = V_{gb} (calculated from V_{1mA} and average grain size), and barrier height (ϕ) at a grain boundary are shown in **Table 1**. ϕ is determined from the change in dielectric constant due to a depletion layer at a p/n interface by using CV (capacitance-voltage) method (Ikoma and Okumura, 1981).

Grain sizes of two types are the same level of 2–4 μm , however, it is evident that V_{gb} and ϕ are considerably different between two types. Pr-doped type is approximately 40% lower V_{gb}/ϕ of 1.07 V/ 0.64 eV than 1.78 V/1.15 eV for Bi-doped, respectively. From these results, it is suggested that two types have different grain boundary characteristics even with a small amount of additives. It is likely that Pr-doped type is able to have low-voltage characteristics due to with lower V_{gb}/ϕ . Therefore, it is believed that lowering of V_{gb} is one development direction for realizing low-voltage varistors below that of Pr-doped.

Effect of Thermal Properties of Compositional Materials on ESD Stability

Because semiconductor devices such as ICs are typically vulnerable to ESD stress, a lot of knowledge has been reported on the ESD withstanding. Especially, the thermal property of the interface of the p/n junction is found to be closely related with stability to

ESD of devices (Wunsch and Bell, 1968). From the results, since nonlinearity of varistors is due to the same Schottky barriers as that of ICs, it is considered that the knowledge on ESD stability should be applicable to varistors. The equation derived from the Wunsch & Bell model is well known to be in good agreement with ESD withstanding of Schottky barriers in semiconductor devices. From this equation, capability of power withstanding per unit area of devices vs. an applied pulse width is indicated by a slope of 1/2 power, and the level of withstanding is determined by the melting point of material at an interface. On the basis of this knowledge, in the same way, ESD stability of varistors can be predicted to be improved in proportion to the melting point of the interfacial material (i.e., in grain boundaries). Melting points of compositional materials in Bi- and Pr-doped varistors are shown in Fig. 3 with those of Si in ZDs. The melting points of Bi_2O_3 and Sb_2O_3 in Bi-doped varistors are 820°C and 656°C, respectively. On the other hand, Pr_6O_{11} and Co_2O_3 in Pr-doped have melting temperatures of above 1900°C. In addition, Si in ZDs melts at about 1470°C. From their results, the melting points of interfacial materials are found to correspond well to the degree of ESD stability. Therefore, it can be seen that higher melting points of the compositions added to ZnO lead to high ESD stability in varistors (Koga et al., 2012). Furthermore, as ZnO varistors are polycrystalline ceramics, an applied voltage would be shared by each grain boundary along electric field vectors. In consequence, we believe that the lowering of the grain boundary voltage (i.e., V_{gb}) increases the number of grain boundaries, being effective in improving ESD withstanding.

Novel Low-Voltage ZnO Varistor Material With ESD Withstanding

Recently, from our studies on many varistors with lower V_{gb} and higher melting points of grain boundary compositions, we have successfully developed novel SrCoO_3 -doped ZnO varistors, which have low-voltage characteristics and strong ESD stability. The investigation of developed material is described in this section.

P-type conductive oxides, which can form Schottky barriers, are candidates for the grain boundary composition between ZnO grains of n-type semiconductor. Of those, $\text{ACoO}_{3-\delta}$ ($A = \text{Ca}, \text{Sr}, \text{and Ba}$) of perovskites in particular are P-type compounds with high melting point, and their doped ZnO is found to exhibit high nonlinearity (Koga et al., 2011, 2012). $V_{1\text{mA/mm}}$, $\alpha_{10\text{ }\mu\text{A}}$, V_{gb} and grain size of $(1-x)\text{ZnO} + x\text{ACoO}_{3-\delta}$ ($x = 0.005 \sim 0.02$) are summarized in Table 2. Precursors of $\text{ACoO}_{3-\delta}$ are prepared by solid-reaction method. They are added to ZnO powder, and mixed by ball milling method. Then, ACoO_3 -doped ZnO varistors have been produced under the optimized sintering condition so as to have high nonlinearity for each composition. As shown in Fig. 2, the new system of varistors exhibits low-voltage characteristics than those of conventional types, maintaining the same level of nonlinearity ($V_{1\text{mA/mm}} = 260\text{--}360\text{ V}$, $\alpha_{10\text{ }\mu\text{A}} = 1.27\text{--}1.4$). Furthermore, two types of varistors for $A = \text{Ca}$ and Ba have V_{gb} of 1.23 and 1.17 V, which are the intermediate values between Bi- and Pr-doped types. Whereas, it is noted that V_{gb} of SrCoO_3 -doped ZnO varistors (i.e., $A = \text{Sr}$)

Fig. 3 Melting temperatures of each oxide in Bi/Pr-based varistor compositions and of zenor diodes.

Table 2 Characteristics of ACoO_3 -doped ZnO varistors ($A = \text{Ca}, \text{Sr}, \text{Ba}$)

A	$V_{1\text{mA/mm}}$ V	$\alpha_{10\text{ }\mu\text{A}}$ $V_{1\text{ mA}}/V_{10\text{ }\mu\text{A}}$	V_{gb} V	Grain size μm
Ca	350	1.19	1.23	3.5
Sr	360	1.19	0.81	2.3
Ba	260	1.42	1.17	7.3

is $\sim 25\%$ lower value ($= 0.81$ V) than that of Pr-based. It is evident from the result that the V_{gb} is the lowest in ZnO varistors. In addition, owing to the small grain size of $2\text{--}3\text{ }\mu\text{m}$, SrCoO₃-doped ZnO varistors are suitable for MLCVs. It is suggested from the results that electrical properties obtained from SrCoO₃-doped ZnO varistors show the possibility of low-voltage MLCVs with strong ESD stability.

MLCVs Using SrCoO₃-Doped ZnO Varistors

Multilayer SrCoO₃-doped ZnO varistors, with the size of $1.0 \times 0.5 \times 0.5$ mm in length, width, and height and $V_{1\text{mA}} = 5.6$ V (about 30% lower than 8 V of conventional MLCVs) are commercially produced. The precious metal is used as the internal electrode within MLCVs. The thickness of varistor layers between electrodes is approximately $17\text{ }\mu\text{m}$ (average number of grains: about 7 pcs.). The capacitance is designed to be 100 pF at 1 MHz, which is general in signal line applications. Fig. 4(a) and (b) shows V – I characteristics for MLCVs of SrCoO₃-doped ZnO varistors in addition to Bi- and Pr-doped types, and the change rate of $V_{1\text{mA}}$ ($\Delta V_{1\text{mA}}$) before and after ESD testing. The ESD testing for MLCVs is carried out at a peak voltage of 8 kV for waveforms under IEC 61000-4-2 standard (level 4).

MLCVs using SrCoO₃-doped ZnO varistors exhibit higher nonlinearity even in the low current region than those of conventional Bi/Pr-doped types, maintaining high insulation between 10 nA and 1 A. This is an important characteristic that leads to the reduction of leakage current when being mounted in equipment. The low-voltage V – I property should be attributed to the reduction of individual V_{gb} . From results obtained, we have confirmed that even after the ESD test, MLCVs have not only $\Delta V_{1\text{mA}}$ less than 10% but also the highest level of ESD stability. This is probably caused by the effect of increasing melting points of the grain boundary compound, which is our development direction described above. In addition, the ESD voltage is shown to be suppressed 1100 V (without MLCVs) to 80–90 V. This suppression effect can be applicable to devices that are vulnerable to ESD (i.e., LED etc.), and would lead to the expansion of a range of applications of MLCVs.

Ultralow-Capacitance MLCVs With a Discharge Cavity

High-speed communication circuits require ultralow capacitance (e.g., 0.1 pF) for devices such as MLCVs. However, lowering capacitance is usually due to the reduction of electrode area in conventional MLCVs. Thus, in case of the measure, it remains the problem that ESD stability and suppression effect cannot both be achieved with high levels. Until now, the lower limit of capacitance of conventional MLCVs has been 0.8 pF, and the suppression voltage is about 600 V at 8 kV under IEC 61000-4-2 standard. To achieve significant improvements in performance, ultralow-capacitance MLCVs ($= 0.1$ pF) have been developed, which have a discharge cavity formed by porous varistors in the internal structure (Koga *et al.*, 2012, 2013). Figs. 5 and 6 show the schematic of the structure and the ESD suppression effect at an ESD pulse voltage of 8 kV. Then, in Table 3 it is shown in comparison with the characteristics of conventional MLCVs as well. Porous SrCoO₃-doped ZnO varistor material with connected pores is formed in the region between counter electrodes. Due to the structure, an ESD pulse can be discharged in the connected pores. Furthermore, low-temperature cofired ceramics (LTCCs) with low dielectric constant ($\epsilon_r = 10$), except for the varistor region,

Fig. 4 Electrical properties of MLCVs of SrCoO₃-doped ZnO varistors with low varistor voltage ($V_{1\text{mA}} = 5.6$ V). (a) V – I properties and (b) $\Delta V_{1\text{mA}}$ after applying of ESD (8 kV under IEC 61000-4-2 standard [level 4]).

Fig. 5 Schematic of cross section of novel MLCVs with ultralow capacitance (e.g., 0.1 pF).

Fig. 6 Suppression wave shape for ESD at 8 kV (IEC 61000-4-2).

Table 3 Characteristics of low capacitance type of novel MLCVs

	Shape mm	Capacitance (typ.) at 1 MHz pF	Suppression voltage (typ.) at 8 kV V	ESD stability *IEC610004-2 kV
Ultralow-capacitance MLCVs (discharge type)	0.6 × 0.3 × 0.3	0.1	200	15
Conventional	1.0 × 0.5 × 0.5	0.8	600	8

are used to improve the mechanical strength and reliability as well as to reduce a stray capacitance. The device size of (length, width, and height) $0.6 \times 0.3 \times 0.3$ mm is ultracompact, and thus suitable for ICT applications.

The typical capacitance is 0.1 pF, which is reduced to about 1/8 of those of conventional MLCVs. Furthermore, the suppression effect is considerably improved from 600 V to 200 V (1100 V without MLCVs). Since $\text{SrCoO}_{3-\delta}$ contains Sr as an alkaline earth metal, it is likely that the work function is as small as 1.0–1.5 eV, which promotes discharge action during an ESD event. Therefore, in an ESD stress event, it is possible to start discharge immediately from a low-voltage level (e.g., 150 V), leading to the high suppression effect.

In the case of the conventional planar gap type, the counter electrodes wear out with every discharge and the gap distance is expanded. As the result, the suppression voltage rises. On the contrary, even after ESD pulse is repeatedly applied to the developed MLCVs (e.g., 100 times), there is no such deterioration. Since the ESD energy is almost consumed within the discharge cavity (i.e., the connected pores), the load to the varistor material results in drastically reducing.

In addition, insertion loss (I_L) is less than 0.1 dB (at 2.5 GHz), being able to operate stably even at a power level of 35 dBm. Thus, the influence on transmission characteristics can be extremely small. Due to the effect, high protection performance is obtained even for high-speed transmission lines for the antenna of mobile phones. The application of the $\text{SrCoO}_{3-\delta}$ -doped ZnO

varistor material to MLCVs with a discharge cavity has been found to give both excellent ESD suppression effect and high reliability to ESD, which have ultralow capacitance of 0.1 pF.

MLCVs Cofired With Internal Electrodes of Base Metal

In this section, we describe the new approach of realization of MLCVs with base metal as internal electrodes. As the cost of electrodes (precious metals) is very high in conventional MLCVs, the impact of application of base metal to internal electrodes should be very significant. With the minimization of adoption barriers by price, the range of applications of MLCVs is remarkably expanded. To produce MLCVs with internal electrodes of base metal, atmosphere below the equilibrium oxygen partial pressure is essential for cofiring with base metal electrode. However, Bi- and Pr-doped types cannot be used because oxygen is removed from grain boundaries, and thus nonlinearity disappears easily. On the other hand, SrCoO₃-doped ZnO varistors are found to exhibit excellent nonlinear V - I characteristics by air-annealing even after sintering in a reducing atmosphere (Higashi *et al.*, 2015). Furthermore, sufficient nonlinearity and ESD stability for practical use can be obtained from MLCVs with internal electrodes of base metal (Cu). Research on the MLCVs is described below.

Nonlinearity of SrCoO₃-doped ZnO Varistors Co-fired With Base Metal

As mentioned above, SrCoO₃-doped ZnO varistors exhibit high nonlinearity by postannealing after reduction (Higashi *et al.*, 2015). Such annealing for reducing sintered bodies is conducted also for SrTiO₃-based varistors to develop nonlinear property by

Fig. 7 V - I properties of bulk bodies of SrCoO₃-doped ZnO varistors taken from as-sintered in a reducing atmosphere and postannealed at 700°C in air.

Fig. 8 Varistor properties of bulk bodies of SrCoO₃-doped ZnO varistors postannealed at various temperatures (300°C–1000°C) in N₂ (O₂ = 0.02%), (a) $V_{1mA/mm}$ and (b) $\alpha_{10 \mu A}$. Two types of sintered samples are shown: the bare bulk disk and a cofired disk with Cu on its upper and lower surfaces.

oxygen diffusion to grain boundaries (Ogasawara and Ogasawara, 1997). The nonlinearity variation by heat treatment is shown in detail here. Fig. 7 shows V - I characteristics of $\text{SrCoO}_{3-\delta}$ -doped ZnO varistors before and after air-annealing (700°C -0.5 h), which are sintered in a reducing atmosphere. As shown in the figure, the low ohmic resistance of as-sintered MLCVs changes to high nonlinear characteristics of $V_{1\text{mA/mm}} = 1240\text{ V}$ and $\alpha_{10\text{ }\mu\text{A}} = 1.19$ by annealing Higashi *et al.*, (2015). The development of nonlinearity during the annealing process is demonstrated in Fig. 8(a) ($V_{1\text{mA/mm}}$) and (b) ($\alpha_{10\text{ }\mu\text{A}}$). To examine the influence of cofiring with the base metal, cofiring with Cu electrode paste on the green compact are performed as well. Regardless of cofiring with Cu, $V_{1\text{mA/mm}}$ increases with an increase of the annealing temperature, and then saturates at around 600°C . $\alpha_{10\text{ }\mu\text{A}}$ improves to < 1.3 by annealing at above 600°C , showing excellent nonlinearity (Higashi *et al.*, 2015). The changes should be attributed to the variation state of electrical barriers formed by the diffusion of oxygen to grain boundaries. Although $V_{1\text{mA/mm}}$ of bulk bodies cofired with Cu decreases slightly by heat treatment above 600°C , the variation is relatively small (-13% at 900°C). From the result, it can be seen that annealing at about 700°C probably is effective to cause sufficient oxygen diffusion to give rise to nonlinear behavior.

Enhancement of Nonlinearity by Increasing P-Type Carriers at Grain Boundaries

It is speculated from results that heat treatment as postannealing diffuses oxygen to $\text{SrCoO}_{3-\delta}$ at grain boundaries, forming electrical barriers causing nonlinearity. Hence, $\text{SrCoO}_{3-\delta}$ should be present as p-type conductivity at interfaces between ZnO grains (n -type). To confirm the speculation, the sintered bulk bodies of $\text{SrCoO}_{3-\delta}$ were heated in a reduction atmosphere, and then air-

Fig. 9 Powder XRD patterns of $\text{SrCoO}_{3-\delta}$: as synthesized, reduction heat treatment, and air-annealing (400°C - 1000°C).

Fig. 10 Air-annealing temperature dependence of the Seebeck coefficient and conductivity of reduced $\text{SrCoO}_{3-\delta}$.

annealing was performed at 400°C–1000°C to evaluate the crystal phase, the carrier type of p/n and conductivity (Higashi and Koga, 2017).

Fig. 9 illustrates powder XRD patterns of $\text{SrCoO}_{3-\delta}$ by various heat treatments (as synthesized, reduction heat treatment, and air-annealing). Synthesized $\text{SrCoO}_{2.52}$ (hexagonal) of the perovskite type structure is mainly decomposed into $\text{Sr}_3\text{Co}_2\text{O}_{6.13}$, SrO , CoO , and Co_3O_4 by the reduction heat treatment (Higashi and Koga, 2017). However, they are resynthesized as matrix phase ($\text{SrCoO}_{2.52}$) of hexagonal with a small amount of extra two structures (orthorhombic and tetragonal as $\text{SrCoO}_{2.5}$) by annealing over 800°C (Higashi and Koga, 2017). Since the weight increases simultaneously in corresponding to the change of crystal phases, it can be seen that oxidation is responsible for reformation of $\text{SrCoO}_{2.5}$ (Higashi and Koga, 2017). Then, Fig. 10 indicates air-annealing temperature dependence of the Seebeck coefficient and conductivity of reduced $\text{SrCoO}_{3-\delta}$ (Higashi and Koga, 2017). Regardless of heat treatment, the Seebeck coefficients are all positive over the range of temperature (400°C–1000°C) studied here. It is evident from the result that annealed $\text{SrCoO}_{3-\delta}$ becomes p-type conductive by generated holes. In particular, the coefficients are found to increase sharply by twice between 700°C and 800°C. It is likely that the temperature range is in good agreement with the reformation temperature of $\text{SrCoO}_{2.52}$ (perovskite like compound) (Higashi and Koga, 2017). In addition, the conductivity shows high values of 10–1000 times that of 600°C in the temperature range of 800°C–1000°C when the $\text{SrCoO}_{2.52}$ is regenerated (1.7×10^{-2} to $3.1 \text{ S} \cdot \text{cm}^{-1}$) (Higashi and Koga, 2017). From these results, it is concluded that $\text{SrCoO}_{3-\delta}$ from compounds decomposed by reduction is regenerated by air-annealing, and the p-type carrier concentration increases with the oxidation. The increase of p-type carriers in grain boundaries should be the origin of the electrical barriers between ZnO grains (n-type), causing nonlinearity (Higashi et al., 2015); (Higashi and Koga, 2016, 2017).

MLCVs Cofired With Internal Electrodes of Base Metal

In this last section, we would like to introduce some of the results of first realizing MLCVs cofired with base metal internal electrodes by the combination of reduction sintering and oxygen diffusion control. V – I characteristics and ESD stability, which are available for practical use, could be realized for MLCVs cofired with Cu internal electrodes, using SrCoO_3 -doped ZnO varistors (Higashi et al., 2015). The device size is $1.0 \times 0.5 \times 0.5 \text{ mm}$ in length, width, and height, and the varistor-layer thickness within MLCVS is $17 \mu\text{m}$. After sintering in the same reducing atmosphere as in the evaluation of bulk disks, air-annealing is carried out at 700°C for 0.5 h. Nonlinear characteristics of $V_{1\text{mA}} = 22.4 \text{ V}$ and $\alpha_{10\mu\text{A}} = 1.44$ are obtained by the procedure process. When normalized to $V_{1\text{mA}}/\text{mm}$, it is 1320 V, which is almost the same level as that of the bulk body ($V_{1\text{mA}}/\text{mm} = 1240 \text{ V}$, $\alpha_{10\mu\text{A}} = 1.19$) (Higashi et al., 2015). Furthermore, it is confirmed that the capacitance also increases in proportion to the number of multilayers. This suggests that the function of the Cu internal electrode is effective from the expansion effect of the electrode area (Higashi et al., 2015).

Finally, we describe protection performance of the MLCVs cofired with internal electrodes of base metal. The important characteristics for ESD suppression performance, is of a large current region of above 1 A, that is, the bulk resistance of ZnO grains (Higashi and Koga, 2016). The conductivity of ZnO is due to oxygen vacancies, which significantly depend on P_{O_2} in sintering. Fig. 11 gives the relationship between P_{O_2} and ESD stability after zapping at a voltage of 8 kV. When sintered in $P_{\text{O}_2} = 1.0\text{--}1.6 \times 10^{-9} \text{ MPa}$, high ESD stability has been obtained, which gives a small $\Delta V_{1\text{mA}}$ (less than $\pm 10\%$) (Higashi et al., 2015). At higher P_{O_2} ($> 1.6 \times 10^{-9} \text{ MPa}$), Cu of the internal electrode diffuses into the ZnO grains, increasing the electrical resistance. Increasing resistance leads to cause the degradation of stability to ESD, due to heat generation after ESD stress (Higashi et al., 2015). On the other hand, in the case of low P_{O_2} below $1.6 \times 10^{-9} \text{ MPa}$, although the resistance of grains decreases, ZnO drastically evaporates by strong reduction, and the density of sintered MLCVs decreases (Higashi et al., 2015). Consequently, the internal electrodes diffuse and oxidize within MLCVs during the heat treatment, that cause the resistance deterioration in the low current region. Though practical V – I characteristics could be obtained, ZnO evaporation on the surface is one of the issues (i.e., reliability) for commercial realization of MLCVs produced by reduction sintering. Since the low density in the surface layer gives rise to the degradation of reliability such as in humidity, it is necessary to study the processing and coating to reduce the vaporization of Zn from MLCVs.

Fig. 11 The relationship between P_{O_2} and $\Delta V_{1\text{mA}}$ as ESD stability after zapping at a voltage of 8 kV.

Summary

To resolve the issues for protection from overvoltage, we have developed not only a new material system of SrCoO₃-doped ZnO varistors but also MLCVs using the same. In addition, MLCVs with base metal internal electrodes have been realized as well, for the first time. The findings obtained are listed below.

- (1) V_{gb} of SrCoO₃-doped ZnO varistor material is 30% lower than those of conventional two types of Bi/Pr-doped. The MLCVs have low-voltage characteristics ($V_{1mA} = 5.6$ V) below the conventional limit (8 V) and strong ESD stability (level 4 in IEC 61000-4-2).
- (2) For application to high-speed and high-frequency circuits, we have developed MLCVs with a discharge cavity in the structure, to give ultralow capacitance (0.1 pF), high ESD suppression effect (1100 V to 200 V), and high ESD withstanding.
- (3) V - I characteristics with practical use can be provided to MLCVs by the combination of sintering in a reducing atmosphere and air-annealing. The increase in p-type carriers of SrCoO_{3-δ} at grain boundaries should be the origin of the nonlinearity caused by air-annealing.
- (4) By the control of P_{O_2} in sintering and annealing temperature, practical V - I characteristics and ESD stability is provided to MLCVs with Cu internal electrodes.

Finally, we emphasize that recent studies reported in this paper can contribute to the development of protection performance against overvoltage. Further contributions will achieve both novel material development and device technology.

Dielectric, Ferroelectric, Antiferroelectric, Relaxor, Piezoelectric Ceramics: Definitions and Main Applications

Floriana Craciun, Institute of Structure of Matter-CNR, Rome, Italy

© 2021 Elsevier Inc. All rights reserved.

Introduction

The field of multifunctional applications is mainly based on dielectric ceramics, which, depending on their structure and composition, show appealing dielectric, ferroelectric, piezoelectric, and optical properties. Different types of dielectric ceramics have been developed, including thin ceramic films for microdevices. In this chapter, the dielectric crystalline media properties for different structures are defined and the main types of dielectric ceramics interesting for applications are presented. In the second section, basic concepts related to dielectrics, piezoelectric, ferroelectric, antiferroelectric, and relaxor ceramics are introduced.

The effect of crystal symmetry on the reduction of the number of independent piezoelectric moduli in piezoelectric materials is considered. It is shown that the effective properties of ferroelectric ceramics are different from those of monodomain single crystals, and that in the first approximation they can be obtained by averaging over the various orientations of the domains in the crystallites. Nonlinear properties of ferroelectric ceramics are presented.

Phase transitions in ferroelectrics and antiferroelectrics in terms of the phenomenological theory of Landau and Lifshitz (1960) are discussed, together with a brief presentation of some microscopic models and first-principles methods. The origin of the ferroelectric effect is briefly discussed, and a short discussion of ferroelectric phase transitions in the frame of the soft mode theory (Binc and Zeks, 1974) is included.

Relaxor ferroelectrics are presented. Most recent models regarding the origin, structure, and behavior of nanopolar regions are discussed.

In the third section, some of the most recent and diffused technological applications of these materials are presented.

Basic Concepts

Dielectrics

From the point of view of electrical properties, materials are divided into two categories: conductors and dielectrics. In an electric field, the first allow a flow of electric charges while the second do not allow this flow. Thus, the fundamental property of dielectrics consists in the impossibility of flowing of a continuous electrical current in them. Therefore, an electrical field can exist in the internal of a dielectric (Landau and Lifshitz, 1960). The equations governing this behavior (in the absence of magnetic field) are the classical Maxwell's equations:

$$\nabla \times \vec{E} = 0 \quad (1)$$

$$\nabla \cdot \vec{E} = \frac{\rho}{\epsilon_0} \quad (2)$$

where ρ is the total electric charge density and ϵ_0 is the permittivity of free space.

When a dielectric is introduced in an electric field, the total net charge remains null, that is $\int \rho dV = 0$. This means that average charge density for a dielectric body can be written as the divergence of a vector $-\vec{P}$ (Landau and Lifshitz, 1960):

$$\rho = -\nabla \cdot \vec{P} \quad (3)$$

$\vec{P}$ is called the polarization vector. Following Landau and Lifshitz (1960), for the determination of the physical meaning of $\vec{P}$, we consider the moment of the total dipole of all the charges inside the dielectric. Unlike the total charge, this quantity may not be null. According to the definition of the dipole moment, this quantity is the integral $\int \rho \vec{r} dV$. It can be shown that by substituting the charge density from Eq. (3) and integrating over the volume which contains the material, one obtains:

$$\int \rho \vec{r} dV = \int \vec{P} dV \quad (4)$$

Thus, the polarization vector represents the dipole moment of the volume unit of the dielectric, $\vec{P} = \rho \vec{r}$. It must be mentioned, however, that the usual definition of the macroscopic electric polarization of a crystal as the dipole per unit cell is correct only for the ionic models, where the dielectric solid is considered as formed by separated and independent polarizable units. Any attempt to apply it to covalent solids, where the electronic charge is delocalized, results into an incorrect definition (Resta, 1994).

By using Eqs. (2) and (3), Eq. (2) can be written in the form:

$$\nabla \cdot \vec{D} = 0 \quad (5)$$

where a new quantity $\vec{D}$ defined as:

$$\vec{D} = \epsilon_0 \vec{E} + \vec{P} \quad (6)$$

has been introduced. $\vec{D}$ is called dielectric displacement and it is produced by the small displacement of the bonded charges in the electric field applied on the dielectric body.

At small values of the electric field, a linear relationship between the displacement $\vec{D}$ and the field intensity $\vec{E}$ can be considered, which in the case of an isotropic dielectric, can be written as:

$$\vec{D} = \varepsilon \vec{E} \quad (7)$$

The coefficient ε is called dielectric permittivity of the material and it is a function of its thermodynamic state. Also polarization $\vec{P}$ is proportional to the field:

$$\vec{P} = \chi \varepsilon_0 \vec{E} = (\varepsilon - \varepsilon_0) \vec{E} \quad (8)$$

The quantity $\chi = \frac{\varepsilon}{\varepsilon_0} - 1$ is called dielectric susceptibility.

In an anisotropic dielectric medium the relationship (7) becomes:

$$D_i = D_{0i} + \varepsilon_{ik} E_k \quad (9)$$

where $\vec{D}_0$ is a constant vector and ε_{ik} is the dielectric permittivity tensor. The free term $\vec{D}_0$ is not necessarily present in every crystal, since the majority of crystalline symmetry types do not allow the existence of a constant vector, therefore $D_i = \varepsilon_{ik} E_k$. The tensor ε_{ik} is symmetric, and it can be reduced to the diagonal form with an adequate choice of the coordinate system. Thus, in the general case, the tensor ε_{ik} is defined by three independent quantities ε_{11} , ε_{22} , and ε_{33} . Furthermore, depending on the symmetry of the crystal, the number of the principal values of the tensor ε_{ik} can be further reduced. For example, in crystals of the triclinic, monoclinic, and orthorhombic systems all three principal values are distinct (biaxial crystals), whereas in crystals of the tetragonal, rhombohedral, and hexagonal systems two principal values coincide thus there exists two independent principal values (uniaxial crystals). In crystals of cubic system, all three principal values of tensor ε_{ik} are equal, thus the tensor ε_{ik} reduces to a scalar, like in isotropic materials.

In dielectric materials, there are different mechanisms contributing to polarization: The shift of electronic clouds with respect to nuclei, which is the most important contribution at ultraviolet frequencies, the displacement and deformation of ions with respect to each other, occurring at infrared frequencies and the orientation of polar molecules in the field, occurring generally at microwave frequencies (Kittel, 1966).

In a variable field, there is a lag between the variation of the applied electric field and the response of polarization. Therefore, the dielectric permittivity is generally dependent on frequency, $\varepsilon = \varepsilon(\omega)$, a phenomenon that is called dispersion. The delayed response of the dielectric material with respect to the applied electric field is called dielectric relaxation. For a simple, non-interacting dipole system, it is expressed by the Debye equation:

$$\varepsilon(\omega) = \varepsilon_\infty + \frac{\Delta\varepsilon}{1 + i\omega\tau} \quad (10)$$

where ε_∞ is the permittivity at ultrahigh frequencies and τ is the relaxation time. The real and imaginary parts of the complex dielectric permittivity $\varepsilon(\omega) = \varepsilon'(\omega) + i\varepsilon''(\omega)$ are given by:

$$\varepsilon'(\omega) = \varepsilon_\infty + \frac{\Delta\varepsilon}{1 + \omega^2\tau^2} \quad (11)$$

$$\varepsilon''(\omega) = \frac{\Delta\varepsilon \omega\tau}{1 + \omega^2\tau^2} \quad (12)$$

The ratio of the imaginary and real parts of the dielectric permittivity, $\tan \delta(\omega) = \frac{\varepsilon''(\omega)}{\varepsilon'(\omega)}$, is called dielectric loss and it represents an important quality factor for dielectric materials.

High dielectric permittivity ceramics with low dielectric loss, like SrTiO_3 , $(\text{Ba,Sr})\text{TiO}_3$, Ta_2O_5 , TiO_2 , etc., have been developed especially as thin films, for use in high capacitance devices, microwave applications, very large scale integration circuits, etc.

Piezoelectrics

In a crystal without center-of-inversion symmetry (noncentrosymmetric), an applied strain results into a net macroscopic electrical polarization, due to changes in the charge distribution produced by the applied strain. This is called direct piezoelectric effect. In piezoelectric materials also the converse effect, where the crystal is strained by the application of an electric field, is present.

Consider a dielectric medium immersed in an electric field. Generally, the internal stresses which occur in an isotropic dielectric immersed in an electric field are a quadratic effect with respect to the field (electrostrictive effect). But in piezoelectrics, these internal stresses are proportional to the first power of the electric field.

In the macroscopic theory of piezoelectricity, it is often convenient to use the electric field E_i and the stress tensor T_{ik} as independent variables. By using the thermodynamic potential for a piezoelectric medium (Landau and Lifshitz, 1960):

$$\Phi = \Phi_0 - \frac{1}{2} s_{iklm} T_{ik} T_{lm} - \frac{1}{2} \varepsilon_{ik} E_i E_k - E_i D_{i0} - d_{i,kl} E_i T_{kl} \quad (13)$$

where s_{iklm} is the elastic susceptibility (compliance) tensor and $d_{i,kl}$ is the piezoelectric strain tensor; the deformation tensor components S_{ik} and the dielectric displacement vector components D_i are expressed as:

$$S_{ik} = - \left(\frac{\partial \Phi}{\partial T_{ik}} \right)_E = s_{iklm} T_{lm} + d_{i,ik} E_l \quad (14)$$

$$D_i = - \left(\frac{\partial \Phi}{\partial E_i} \right)_T = D_{i0} + \varepsilon_{ik} E_k + d_{i,kl} T_{kl} \quad (15)$$

The above relations are the constitutive equations for the piezoelectric medium. The direct piezoelectric effect is described by the last term in the second equation, while the converse piezoelectric effect is described by the last term in the first equation. In the second equation, the term D_{i0} is related to the spontaneous polarization, which can be present in some classes of piezoelectrics, as it will be discussed later.

Before introducing other sets of constitutive equations, written for different couples of independent variables, let us see briefly which types of crystalline symmetries allow the existence of piezoelectricity and which are the effects of symmetry restrictions on the components of piezoelectric tensor.

Since $T_{kl} = T_{lk}$, it means that also $d_{i,kl}$ is symmetric in the last pair of indices. This leaves us with 18 independent components, among the 27 components of the third rank piezoelectric tensor. This number is further reduced by the crystal symmetry transformations, which must leave invariant the tensor components. A trivial result is that the material cannot be piezoelectric if it is centrosymmetric. Among the 32 crystalline classes only 20 admit piezoelectricity. These include the 10 pyroelectric classes which will be discussed later on, plus another 10 classes: D_2 belonging to the rhombic system, D_4 , D_{2d} , S_4 (tetragonal), D_3 (rhombohedral), D_6 , C_{3h} , D_{3h} (hexagonal), and T , T_d (cubic).

It is convenient to use a more concise notation, called the matrix notation, which condenses the couple of indices (kl) according to the following rules: (kl) $\rightarrow$ (k) for $k = l = 1, 2, 3$ while (kl) for $k \neq l$ transforms as follows: ((23), (31), (12)) $\rightarrow$ (4,5,6).

With these notations the constitutive equations written above become:

$$S_\alpha = s_{\alpha\beta}^E T_\beta + d_{i\alpha} E_i \quad (16)$$

$$D_i = \varepsilon_{ik}^T E_k + d_{i\beta} T_\beta \quad (17)$$

where $i = 1, 2, 3$ and $\beta = 1, 2, \dots, 6$.

The crystal symmetry operations reduce the number of independent piezoelectric moduli. The vanishing and the equality of many of the moduli in the various classes can be deduced in this way. Another approach is to transform the axes of reference of the tensor by one of the symmetry elements possessed by the crystal. After the operation, the transformed piezoelectric coefficients must remain unchanged.

By applying these rules, the independent piezoelectric moduli of all classes can be found (Nye, 1985). For example, for quartz the d_{ij} matrix is: $d_{11}, d_{12} = -d_{11}, d_{14}, d_{25} = -d_{14}, d_{26} = -2d_{11}$, all other moduli being zero. For crystals in the hexagonal 6 mm (C_{6v}) class the d_{ij} matrix is: $d_{31} = d_{32}, d_{33}, d_{15} = d_{24}$, all other moduli being zero.

As previously mentioned, three other sets of constitutive equations are derived from other thermodynamic potentials:

$$S_\alpha = s_{\alpha\beta}^E T_\beta + g_{i\alpha} D_i \quad (18)$$

$$E_i = \beta_{ik}^T D_k - g_{i\beta} T_\beta \quad (19)$$

$$T_\alpha = c_{\alpha\beta}^E S_\beta - e_{i\alpha} E_i \quad (20)$$

$$D_i = \varepsilon_{ik}^S E_k + e_{i\beta} S_\beta \quad (21)$$

$$T_\alpha = c_{\alpha\beta}^D S_\beta + h_{i\alpha} E_i \quad (22)$$

$$E_i = \beta_{ik}^S D_k - h_{i\beta} S_\beta \quad (23)$$

where $c_{\alpha\beta}$ are the elastic stiffness constants, β_{ik} are the dielectric stiffness constants, $g_{i\alpha}$ and $e_{i\alpha}$ are the piezoelectric voltage and piezoelectric stress constants, and $h_{i\alpha}$ are other piezoelectric coefficients. The superscripts E and D indicate the measurement conditions: under constant electric field or under constant charge, while T and S mean constant stress or constant strain.

The different coefficients measured under different conditions are not independent but they are related by various relationships. Thus, the following relations exist between the piezoelectric matrix coefficients (Wersing, 2008):

$$[d] = [e] [s^E] = [e^T] [g] \quad (24a)$$

$$[e] = [d] [c^E] = [e^S] [h] \quad (24b)$$

$$[g] = [h] [s^D] = [\beta^T] [d] \quad (24c)$$

$$[h] = [g] [c^D] = [\beta^S] [e] \quad (24d)$$

Detailed form of matrices can be found in Nye (1985) and IEEE Standard on Piezoelectricity (1988).

Besides the coefficients obtained from thermodynamic potentials, which represent material properties, in Eqs. (16–23), another important system of derived coefficients is represented by the electromechanical coupling factors, which describe the

strength of the conversion electrical $\leftrightarrow$ mechanical energy (IEEE Standard on Piezoelectricity, 1988). Thus:

$$k_{33}^2 = \frac{d_{33}^2}{\epsilon_{33}^T s_{33}^E} \quad (25)$$

The same type of relationship is valid also for k_{31} and k_{15} : $k_{31}^2 = \frac{d_{31}^2}{\epsilon_{33}^T s_{11}^E}$ and $k_{15}^2 = \frac{d_{15}^2}{\epsilon_{11}^T s_{55}^E}$.

The following relation is also valid: $k_{33}^2 = \frac{s_{33}^E - s_{33}^D}{s_{33}^E}$.

The piezoelectric constants are generally determined by quasistatic (Berlincourt type) methods or by the resonance method, in which samples of selected types are excited to resonance by an alternate electric field and the resonance values are used to calculate the various constants (IEEE Standard on Piezoelectricity, 1988; Wersing, 2008). The dielectric, elastic, and piezoelectric coefficients of piezoelectric ceramics are generally determined with small driving signals.

Another method consists in measuring the whole impedance spectrum of the sample and fitting the curves with parameters related to the physical properties (dielectric permittivity, elastic constants, and piezoelectric coefficients). Thus, one can use more points on the impedance curve to obtain the material properties with higher precision. Moreover, in this way it is possible to determine both the real parts as well as the imaginary parts of the coefficients (Smits, 1976).

Ferroelectrics

We discuss now the dielectric properties of crystals with a constant term $\vec{D}_0$ in Eq. (15). This constant vectorial term represents the fact that the dielectric medium is spontaneously polarized even in the absence of an external electric field. These dielectric materials are called pyroelectric. The pyroelectricity can exist only in a crystal which has a direction, that of $\vec{D}_0$ vector, which remains invariant for all the symmetry transformations. Among the 32 crystalline classes, those in which the pyroelectricity exists are triclinic (C_1), monoclinic (C_s , C_2), orthorhombic (C_{2v}), tetragonal (C_4 , C_{4v}), rhombohedral (C_3 , C_{3v}), and hexagonal (C_6 , C_{6v}) system. In a crystal of class C_1 the direction of pyroelectric vector $\vec{D}_0$ is not related to a particular crystallographic direction, for C_s this direction is in the symmetric plane, and in all the other classes the direction is along the symmetry axis. It must be mentioned that when speaking about symmetry conditions, we consider the crystalline medium as illimited. For a finite crystal, the value of its dipole moment can depend (in an ionic crystal) on the crystalline planes crossed by the sample surfaces, that is, on the fact that these planes contain ions of the same sign or are electrically neutral (Landau and Lifshitz, 1960).

In a normal pyroelectric crystal, the variation of the spontaneous polarization direction is associated with a substantial restructuring of the crystalline lattice, due to the high energy barrier between the two states. However, in some materials the positions of the atoms of the crystalline lattice in the pyroelectric phase are only slightly different from the positions in the nonpyroelectric phase. Therefore, the variation of the direction of the spontaneous polarization can occur relatively easily. These crystals are called ferroelectrics.

The ferroelectric properties of a material mainly depend on its crystalline symmetry. The direction of the spontaneous polarization (the ferroelectric axis) is already predetermined by the structure of the nonpyroelectric phase above the transition temperature. The ferroelectric axis can appear only along a well determined crystallographic direction, while in other cases the symmetry of the nonpyroelectric phase allows the occurrence of spontaneous polarization along different crystallographic directions. The appearance of polarization is always related to a decreasing of the crystal symmetry.

There are several approaches to a theory of ferroelectricity. One of these has been developed by Ginzburg in the framework of the general theory of phase transition of second order of Landau and Lifshitz (1960). It has been pointed out (Toledano and Toledano, 1987) that this approach, although phenomenologic, is still successfully employed because it is rigorous for many systems, it is a mathematically simple and flexible theory and it is strongly connected with the statistical theory of critical phenomena.

Within this approach, the dielectric polarization vector $\vec{P}$ is the order parameter whose size determines the degree of deviation of the crystalline lattice structure from the asymmetric to the symmetric phase. This means that $\vec{P}$ will be considered as an independent thermodynamic variable related to the conditions of minimization of the thermodynamic potential.

For the beginning let us consider the case of a unique ferroelectric axis. Near the transition point the order parameter $\vec{P}$ is small and the Landau expansion of the free energy density in powers of P can be considered:

$$G(T, P) = G_0(T) + \frac{1}{2}\alpha(T)P^2 + \frac{1}{4}\beta(T)P^4 + \frac{1}{6}\gamma(T)P^6 + \dots \quad (26)$$

In this expansion only even terms are considered, since the free energy density must be invariant with respect to polarization reversal in the paraelectric phase. Following the treatment in Blinc and Zeks (1974), the equilibrium spontaneous polarization values are obtained at the free energy extreme:

$$\left(\frac{\partial G(T, P)}{\partial P} \right)_{P_s} = 0 \quad (27)$$

which gives the following relation:

$$(\alpha(T) + \beta(T)P_s^2 + \gamma(T)P_s^4)P_s = 0 \quad (28)$$

The trivial solution $P_s = 0$ corresponds to the paraelectric phase. Other stable solutions are those that correspond to extreme minimum points of free energy, given by the condition:

$$\left(\frac{\partial^2 G(T, P)}{\partial P^2}\right)_{P_s} > 0 \quad (29)$$

Since the second derivative of the free energy density with respect to P is the inverse dielectric susceptibility χ^{-1} , the stability condition can be written as:

$$\chi^{-1} = \alpha(T) + 3\beta(T)P_s^2 + 5\gamma(T)P_s^4 > 0 \quad (30)$$

In the paraelectric phase, $P_s = 0$ and the condition of stability is:

$$\chi^{-1} = \alpha(T) > 0 \quad (31)$$

that is the first coefficient in the free energy expansion $\alpha(T)$ must be positive in the paraelectric phase. The limit of stability of the paraelectric phase is found at a temperature T_0 where $\alpha(T) = 0$. In the neighborhood of T_0 the coefficient $\alpha(T)$ can be developed into a Taylor series in powers of $(T - T_0)$. It is sufficient to keep only the first order term:

$$\alpha(T) = \alpha_0(T - T_0) \quad (32)$$

where α_0 is a positive constant.

From Eqs. (31) and (32), a Curie-Weiss law for the dielectric susceptibility in the paraelectric phase can be written:

$$\chi = \frac{1}{\alpha_0(T - T_0)}, \quad T > T_0 \quad (33)$$

We can further neglect the variation with temperature of β and γ coefficients. It is assumed also that $\gamma > 0$, otherwise higher order terms in Eq. (26) should be considered. Furthermore, depending on the sign of β , different variation (continuous or discontinuous) of the polarization through the transition point and temperature regions of stability for the ferroelectric phase are found.

Consider first $\beta > 0$. In this case, we can take $\gamma = 0$ without loss of significance, thus the Landau expansion of the free energy becomes:

$$G(T, P) = G_0(T) + \frac{1}{2}\alpha_0(T - T_0)P^2 + \frac{1}{4}\beta(T)P^4 \quad (34)$$

From Eqs. (27) and (29) one obtains:

$$(\alpha_0(T - T_0) + \beta P_s^2)P_s = 0 \quad (35)$$

and

$$\chi^{-1} = \alpha_0(T - T_0) + 3\beta P_s^2 \quad (36)$$

One of the solutions of Eq. (36) is $P_s = 0$, which minimizes the free energy when $T > T_0$. Other solutions corresponding to the region $T < T_0$ are obtained as:

$$P_s = \pm \left(\frac{\alpha_0}{\beta}(T_0 - T)\right)^{1/2} \quad (37)$$

From Eqs. (36) and (37), one obtains the static dielectric susceptibility below T_0 as:

$$\chi = \frac{1}{2\alpha_0(T_0 - T)}, \quad T < T_0 \quad (38)$$

The Curie-Weiss constant above T_0 is two times higher than the value below T_0 .

The stability limit of the ferroelectric phase $\chi^{-1} = 0$ is obtained at $T = T_0$ and coincides with the stability limit of the paraelectric phase. This is a second-order phase transition. Thus, for a second-order phase transition, the spontaneous polarization varies continuously through the transition temperature and increases as the square root of $T_0 - T$ (Eq. 37) below T_0 .

By substituting the solutions of Eq. (35) in the free energy (Eq. 34), the minimum values are obtained. For $T > T_0$ the free energy has one minimum at $P = 0$ while below T_0 it has two minima at $+P_s$ and $-P_s$. In Fig. 1 we show the qualitative dependence of the thermodynamic potential on polarization (a), and the spontaneous polarization and dielectric susceptibility dependences on temperature (b).

From the derivation of free energy in Eq. (34) with respect to P , we find the relationship between the electric field and the polarization (Lines and Glass, 1977):

$$\frac{\partial G(T, P)}{\partial P} = E = \alpha_0(T - T_0) + \beta P^2 \quad (39)$$

The P - E relationship describes stable states together with unstable states with negative permittivity (Lines and Glass, 1977). Only stable states and metastable states of polarization are experimentally measured, forming the so-called hysteresis curve $P(E)$ (Fig. 2). At a value of the applied field called critical field (E_c), the polarization is switched from one direction to the opposite direction. When the field is decreased to zero the polarization remains with a value called remnant polarization.

Following the treatment in Ref. (Blinic and Zeks, 1974), we consider now the case $\beta < 0$.

Fig. 2 Hysteresis curve measured on a ferroelectric ceramic. Modified from Craciun, F., Cordero, F., Ciuchi, I.V., Mitoseriu, L., Galassi, C., 2015. Refining the phase diagram of $\text{Pb}_{1-x}\text{La}_x(\text{Zr}_{0.9}\text{Ti}_{0.1})_{1-x/4}\text{O}_3$ ceramics by structural, dielectric and anelastic spectroscopy investigations. *J. Appl. Phys.* 117, 184103-1-8.

Eq. (28) can be put into the form:

$$(\alpha_0(T - T_0) + \beta P_s^2 + \gamma P_s^4)P_s = 0 \quad (40)$$

In addition to the paraelectric solution $P_s = 0$, this equation has two real solutions:

$$P_s = \pm \left[-\frac{\beta}{2\gamma} \left(1 + \left(1 - \frac{4\alpha_0\gamma}{\beta^2}(T - T_0) \right)^{1/2} \right) \right]^{1/2} \quad (41)$$

$$P_s = \pm \left[-\frac{\beta}{2\gamma} \left(1 - \left(1 - \frac{4\alpha_0\gamma}{\beta^2}(T - T_0) \right)^{1/2} \right) \right]^{1/2} \quad (42)$$

The dielectric susceptibility of the ferroelectric phase is obtained by inserting the expression (41) in Eq. (30):

$$\chi^{-1} = \frac{\beta^2}{\gamma} \left(1 - \frac{4\alpha_0\gamma}{\beta^2}(T - T_0) \right)^{1/2} \left(\left(1 - \frac{4\alpha_0\gamma}{\beta^2}(T - T_0) \right)^{1/2} + 1 \right) \quad (43)$$

The stability limit of the ferroelectric phase obtained for $\chi^{-1} = 0$ gives the following limit temperature:

$$T_1 = T_0 + \frac{1}{4} \frac{\beta^2}{\alpha_0\gamma} \quad (44)$$

Thus, the stability limits of the two phases, paraelectric (T_0) and ferroelectric (T_1) are different, which is the distinctive mark of a first order phase transition. At $T = T_1$ P_s has a finite value, and there is a discontinuous variation of the spontaneous polarization through the transition point, which is another distinctive characteristic of a first order phase transition.

The second solution (42) is real only in the region $T_0 < T < T_1$ and it corresponds to a free energy maximum, therefore it is not considered.

Below T_0 the free energy has two minima corresponding to $\pm P_s$, and for $T_0 < T < T_c$ another local minimum appears at $P_s = 0$, where the ferroelectric phase is still stable and the paraelectric phase is metastable. At $T = T_c$, the free energies of the paraelectric and ferroelectric phase are equal (Blinic and Zeks, 1974; Lines and Glass, 1977). From this condition plus the minimization of free energy the transition temperature T_c is obtained as:

$$T_c = T_0 + \frac{3}{16} \frac{\beta^2}{\alpha_0 \gamma} \quad (45)$$

At T_c the dielectric susceptibility is finite and the spontaneous polarization discontinuously changes from a finite value $P_s = \left(-\frac{3\beta}{4\gamma}\right)^{1/2}$ to zero.

For $T_c < T < T_1$ the minimum at $P_s = 0$ is deeper than the two other minima at $\pm P_s$. In this region, the paraelectric phase is stable, whereas the ferroelectric phase is metastable. Above T_1 only the paraelectric phase remains.

It has been suggested (Cochran, 1960) that the phase transitions in some ferroelectrics are driven by one of the normal vibrational modes of the lattice (soft phonon) which becomes unstable. Its frequency decreases down to zero on approaching the critical temperature T_c and the frozen mode displacements become the order parameter of the transition. For a ferroelectric state, the soft phonon must be polar and must correspond to long wavelength (wavevector $q \rightarrow 0$).

One of the first models for ferroelectricity in perovskites, known as the rattling ion model, was proposed by Slater (1950). The model relies on the relative size of ions in the cell, as, for example, in the case of BaTiO_3 , where Ti ion is too small for the octahedral cage, and therefore the electrostatic forces from the other ions can displace it relatively easily from the center. However, the model cannot explain why almost all ferroelectric perovskites have B-cations with d_0 electronic configuration, like e.g., Ti^{4+} , Zr^{4+} , Nb^{5+} , Ta^{5+} , and Sc^{3+} (Cohen, 1992).

Starting from 1990, in the field of ferroelectrics new computational and experimental results have been obtained by the use of first-principles methods and of new fine experimental techniques.

First-principles methods use fundamental physics principles to compute all materials properties (Cohen, 2008). They are based on the density functional theory within the local density approximation (Cohen, 2008). First-principles calculations of the soft mode potential surface in perovskite BaTiO_3 and PbTiO_3 showed that these methods can predict the ferroelectric behavior, and the following picture of the ferroelectric instability in oxide perovskites has been established (Cohen, 2008): Long-range Coulomb forces favor off-centering, while short-range repulsive forces favor the ideal structure where the atoms are as far apart as possible. It is found that the hybridization between the B-cation d-states and the oxygen p-states reduces this repulsion, allowing the B ions to move off-center. Moreover the Pb lone-pair 6s-states also contribute to the off-centering of the Pb ions.

Actually, the most important piezoelectric materials are ferroelectric ceramics based on the Pb-containing perovskites (Helke, 2008). Different chemical modifications can be made in order to obtain the enhancement of piezoelectric and ferroelectric properties. For example, the binary solid solutions of PbTiO_3 – PbZrO_3 or $\text{Pb}(\text{Zr}_{1-x}\text{Ti}_x)\text{O}_3$ (PZT) perovskites have demonstrated enhancement of properties at the so-called morphotropic phase boundary (MPB) where the ratio of Zr to Ti ions is nearly 53/47 (Jaffe *et al.*, 1971). At the MPB, the competition between the phases (tetragonal T and monoclinic M) is the determinant factor for properties enhancement. The Curie temperature for the MPB compositions is higher than 300°C , which allows the use of these materials at relatively high temperatures (Helke, 2008). In Fig. 3 the phase diagram of PZT, as obtained from different measurements, is shown. The dashed lines represent data taken from Jaffe *et al.* (1971) and (Noheda *et al.*, 2000).

The experimental points marked by triangles have been obtained from measurements of the dielectric and elastic susceptibility versus temperature (Cordero *et al.*, 2013). Besides the MPB between the T and M ferroelectric phases, there is another MPB between orthorhombic antiferroelectric and rhombohedral ferroelectric phases, at low Ti content.

PZT properties can be also further tailored for a broad range of applications, by doping with other elements. Usually doping elements are added in concentrations lower than 3 at%. They can be divided in two groups, and their effects can be opposite, depending on their valence. Thus, dopants with higher valency than the substituted ion act as donors and ions with lower valency act as acceptors. They are called softeners or hardeners, respectively. The charge compensation is obtained by the creation of lead or oxygen vacancies. For example, doping trivalent ions (e.g., La^{3+}) at Pb^{2+} positions or pentavalent ions (Nb^{5+}) at $\text{Zr}^{4+}/\text{Ti}^{4+}$ positions act as donors and are compensated by the formation of lead vacancies, which reduce the lattice strain. Consequently, the domain wall mobility increases, favoring domain reorientation and decreasing the coercive field (Helke, 2008). This softening effect is accompanied by enhanced dielectric permittivity, remnant polarization, and piezoelectric constants. On the other hand, acceptor doping with monovalent ions (e.g., K^+) at Pb^{2+} positions or trivalent ions (Fe^{3+}) at $\text{Zr}^{4+}/\text{Ti}^{4+}$ positions leads to the formation of oxygen vacancies. The oxygen vacancies block the domain wall movement and consequently increase the coercive field. This hardening effect leads to smaller dielectric permittivity and piezoelectric constants, but also to low dielectric and mechanical losses, which are significant quality factors for applications such as piezoelectric transformers, filters, etc.

In ferroelectric ceramics, a poling procedure is necessary in order to orient the different ferroelectric domains which form inside crystallites to minimize the depoling fields and mechanical stresses (Wersing *et al.*, 2008). In ferroelectric piezoelectrics, besides the intrinsic piezoresponse, associated with ion displacements and charge redistribution, there is also an additional extrinsic

Fig. 3 Phase diagram of $\text{Pb}(\text{Zr}_{1-x}\text{Ti}_x)\text{O}_3$. Modified from Cordero, F., Trequattrini, F., Craciun, F., Galassi, C., 2013. Merging of the polar and tilt instability lines near the respective morphotropic phase boundaries of $\text{PbZr}_{1-x}\text{Ti}_x\text{O}_3$. *Phys. Rev. B* 87, 094108-1-9.

contribution resulting from non- 180° (e.g., 90°) domain wall movements (Damjanovic and Demartin, 1997). This is especially important at high intensity fields (of the order of the coercive field) where switching of domains is observed, but at low driving field the contribution is given only by reversible domain wall vibration.

In order to obtain the effective properties of poled polycrystalline ferroelectric ceramics, a simple approach is to neglect the effect of crystallite boundaries and to approximate the medium with an ensemble of domains with different orientations, where the material properties are obtained by averaging over the various orientations of the domains in the crystallites (Wersing *et al.*, 2008). Thus, in the case of the piezoelectric constants:

$$d_{iz}^* = \langle d_{iz} \rangle + \dots \quad (46)$$

By using this averaging procedure, the following expressions have been obtained for the effective piezoelectric constants (Wersing *et al.*, 2008):

$$\begin{aligned} 2d_{31}^* &= 2\langle d_{31} \rangle = (d_{31} + d_{33} - d_{15})\langle \cos \theta \rangle + (d_{31} - d_{33} + d_{15})\langle \cos^3 \theta \rangle \\ d_{31}^* &= \langle d_{33} \rangle = (d_{33} + d_{15})\langle \cos \theta \rangle + (d_{31} - d_{33} - d_{15})\langle \cos^3 \theta \rangle \\ d_{15}^* &= \langle d_{15} \rangle = (d_{33} - d_{31})\langle \cos \theta \rangle + (d_{15} - d_{33} + d_{31})\langle \cos^3 \theta \rangle \end{aligned} \quad (47)$$

where θ is the angle between the 3-axis of a domain (direction of P_3) and the 3-axis of the poled ceramic sample. The effect of the intensity of the poling electric field consists into narrowing the statistical distribution of individual polarization directions in a confined angle, which is related to the poling degree.

Thus it can be observed from these relations that depending on the degree of poling the properties of piezoelectric ceramics can be quite different from those of single domain crystallites and can vary strongly with the degree of poling that is with the intensity of the poling field.

Antiferroelectrics

Within the soft mode theory, the antiferroelectric ordering is due to the condensation of a soft mode at the Brillouin zone boundary (Blinic and Zeks, 1974). The antiferroelectric state is characterized by the appearance of two opposite sublattice polarizations and an increase in the size of the unit cell.

In simple phenomenological models of collinear antiferroelectricity, the two sublattice polarizations are equal to each other. A more complex model, where the two collinear sublattice polarizations P_+ and P_- are independent thermodynamic variables, has been developed by Kittel (1951). Thus, Kittel's model can describe ferroelectric, ferrielectric, and antiferroelectric states, depending on the specific parameters in the thermodynamic potential.

Proceeding in a parallel way to the ferroelectric case (Blinic and Zeks, 1974), the free energy density of a uniaxial antiferroelectric medium is expanded in powers of P_+ and P_- as:

$$G(T, P_+, P_-) = G_0(T) + \alpha (P_+^2 + P_-^2) + \beta P_+ P_- + \gamma (P_+^4 + P_-^4) + \dots \quad (48)$$

where higher order terms and some of the fourth order terms are neglected. This approximation is allowed if $\gamma > 0$.

The equilibrium values of the sublattice polarizations P_{+s} and P_{-s} are determined from the conditions:

$$\left(\frac{\partial G(T, P)}{\partial P_{+}} \right)_{P_{+s}, P_{-s}} = 0, \quad \left(\frac{\partial G(T, P)}{\partial P_{-}} \right)_{P_{+s}, P_{-s}} = 0 \quad (49)$$

which lead to a system of two equations for P_{+s} and P_{-s} :

$$\begin{aligned} 2\alpha P_{+s} + \beta P_{-s} + 4\gamma P_{+s}^4 &= 0 \\ 2\alpha P_{-s} + \beta P_{+s} + 4\gamma P_{-s}^4 &= 0 \end{aligned} \quad (50)$$

With further elaboration of these equations (namely by adding and subtracting them) (Blinic and Zeks, 1974), it is found that the possible solutions of the system are:

- (1) $P_{+s} = P_{-s} = 0$ paraelectric solution
- (2) $P_{+s} = P_{-s} \neq 0$ ferroelectric solution
- (3) $P_{+s} = -P_{-s} \neq 0$ antiferroelectric solution
- (4) $P_{+s} \neq -P_{-s} \neq 0$ ferrielectric solution

Following a similar procedure as for the ferroelectric case, it is found that different possible solutions are stable in different conditions. Thus, it is found that at the stability limit $2\alpha - \beta = 0$ and $2\alpha + \beta > 0$, the system transforms from the paraelectric to the antiferroelectric state. It is further assumed, similar to the ferroelectric case, that near the stability limit the coefficient $2\alpha - \beta$ can be developed into a Taylor series in powers of $(T - T_0)$, which gives:

$$\alpha(T) = \frac{1}{2}\beta + \alpha_0(T - T_0) \quad (51)$$

In these conditions, a transition from the high temperature paraelectric to the low temperature antiferroelectric phase occurs at T_0 . The antiferroelectric solution is found to be:

$$P_{+s} = -P_{-s} = \left(\frac{\alpha_0}{\gamma} (T - T_0) \right)^{1/2} \quad (52)$$

which is stable below T_0 . The stability limits of the paraelectric and antiferroelectric states coincide; therefore, the phase transition is of second order. It is found also that the ferroelectric phase is never stable but a metastable ferroelectric phase can exist for $T < T_0 - \frac{3\beta}{2\alpha_0}$ while the ferrielectric solution always corresponds to a maximum of the free energy and is never stable.

The free energy of an antiferroelectric crystal is close to that of a ferroelectric modification of the same structure (Lines and Glass, 1977). This is the origin of the high permittivity of the antiferroelectrics. The antiferroelectric phase can be switched to ferroelectric by the application of a high intensity electric field. This is called electric field-induced phase switching (Hao et al., 2014).

Fig. 4 shows the typical double hysteresis loop for an antiferroelectric ceramic (Craciun et al., 2015), where the net macroscopic remnant polarization is zero.

The forward phase switching field and the backward switching field are obtained by extrapolation. The phase switching behavior confirms that the antiferroelectric and ferroelectric states are close in energy.

However, the field-induced ferroelectric phase is not stable and can turn back to the antiferroelectric phase by the action of electric field and temperature variations.

The first reported and most known antiferroelectric is PbZrO_3 (Sawaguchi et al., 1951). For lead zirconate, the electric field-induced switching from antiferroelectric to the ferroelectric phase is obtained only at high temperatures, above 210°C (Sawaguchi et al., 1951). At room temperature, the transformation is not possible because the breakdown field is lower than the critical field

Fig. 4 Hysteresis loop for an antiferroelectric ceramic. Modified from Craciun, F., Cordero, F., Ciuchi, I.V., Mitoseriu, L., Galassi, C., 2015. Refining the phase diagram of $\text{Pb}_{1-x}\text{La}_x(\text{Zr}_{0.9}\text{Ti}_{0.1})_{1-x/4}\text{O}_3$ ceramics by structural, dielectric and anelastic spectroscopy investigations. J. Appl. Phys. 117, 184103-1-8.

Fig. 5 Schematic illustration of the energy storage density for antiferroelectrics (b) as compared to ferroelectrics (a), as evaluated from their hysteresis loops. Modified from Hao, X., Zhai, J., Kong, L.B., Xu, Z., 2014. A comprehensive review on the progress of lead zirconate-based antiferroelectrics. *Prog. in Mater. Sci.* 63, 1–57.

for transition. Different dopants in lead zirconate are used to decrease its critical field. The most used are La^{3+} , Ba^{2+} , Ca^{2+} , and Sr^{2+} at the Pb site and Sn^{4+} , Ti^{4+} , and Nb^{5+} at the Zr site (Hao *et al.*, 2014).

Thus, by suitable doping, antiferroelectric materials with low critical field like $(\text{Pb},\text{La})(\text{Zr},\text{Sn},\text{Ti})\text{O}_3$ (PLZST) and $\text{Pb}(\text{Zr},\text{Sn},\text{Ti},\text{Nb})\text{O}_3$ (PNZST) have been obtained (Hao *et al.*, 2013, 2014). Electric field-induced switching occurred at room temperature when the compound had tetragonal structure.

The antiferroelectric–ferroelectric field-induced transition is also a structural transition from orthorhombic or tetragonal to rhombohedral. The primitive cell volume of the ferroelectric (rhombohedral) phase is larger than the corresponding volume of the antiferroelectric (tetragonal) phase. Thus, an antiferroelectric ceramic will expand through the field-induced transformation from antiferroelectric to ferroelectric, providing a strain of nearly 1% (Hao *et al.*, 2014). Conversely, in these materials a pressure-induced transition from ferroelectric to antiferroelectric will be accompanied by huge and sharp charge release. Therefore, antiferroelectric materials have potential applications in high-strain actuators, pulsed voltage suppliers, etc. Other potential applications like pyroelectric detectors, cooling devices, and high energy capacitors are related to their enhanced response to temperature and external electric field changes.

As an example, the higher performance for energy storage in antiferroelectric materials as compared to ferroelectrics is illustrated in Fig. 5.

The energy stored per unit volume of a dielectric can be evaluated from the expression: $W = \int_0^{E_{\max}} P dE$. For hysteretic media like ferro/antiferroelectrics the useful (recoverable) energy W_r (represented by the dark gray area in Fig. 5) is the difference between the total stored energy W_s and the dissipated energy represented by the light gray area enclosed in the hysteresis loop (hysteresis loss).

The energy storage efficiency η is defined as $\eta = \frac{W_r}{W_s}$ (Hao *et al.*, 2014). For linear dielectrics where $P = \chi E \cong \epsilon E$, $W = \frac{1}{2} \epsilon E^2$. It follows that linear dielectrics, which have a small dielectric permittivity, are inferior to polar dielectrics regarding energy storage. Moreover, antiferroelectrics have superior storage performance over ferroelectrics, due to their higher recoverable energy. Progress in this field was achieved rapidly with miniaturization of thin films ($W_r = 56 \text{ J cm}^{-3}$) (Hao *et al.*, 2014).

Relaxor Ferroelectrics

Relaxor behavior can be found in materials with different compositions and structures, which generally do not show a phase transition, behaving more like glasses (Mydosh, 2015). Their common characteristic is a broad freezing transition associated with a frequency dependent maximum of some response (Cohen, 2008), be it magnetic (magnetic spin glasses (Sherrington, 2018; Vincent and Dupuis, 2018)), dielectric (dielectric glasses (Kleemann and Dec, 2018)) or elastic (strain glasses (Ji *et al.*, 2018)).

Solid solutions between ferroelectrics and dielectric relaxors, called relaxor ferroelectrics, have been intensively investigated in recent decades, due to their enhanced dielectric and piezoelectric properties. Alternatively, relaxor ferroelectrics have been obtained by doping classical ferroelectrics like PZT with different elements, e.g., La^{3+} on the A-site. A review of relaxor ferroelectrics can be found in Bokov and Ye (2006). Under field cooling, a transition from the relaxor to the ferroelectric phase is obtained. In some relaxor ferroelectric crystals like $\text{Pb}(\text{Mg}_{1/3}\text{Nb}_{2/3})\text{O}_3\text{--PbTiO}_3$ (PMN–PT) and $\text{Pb}(\text{Zn}_{1/3}\text{Nb}_{2/3})\text{O}_3\text{--PbTiO}_3$ (PZN–PT), a huge electromechanical coupling coefficient has been obtained for compositions near the MPB (Park and Shrout, 1997) and for particular orientation of the polar axis and applied electric field. This has been attributed to the polarization rotation (Cohen, 2006).

Relaxor ferroelectrics show a broad-frequency dependent maximum in the dielectric permittivity curves measured as a function of temperature, as shown in Fig. 6. The thin lines are results of fitting with a model described in Cordero *et al.* (2005).

Different models have been proposed to explain the peculiar behavior of relaxor ferroelectrics. Almost all are related with the presence of polar nanoregions (PNRs), although they disagree when the PNRs' true origin, and especially the nature of the embedding matrix, are discussed.

Recent molecular dynamic simulations (MDS) have shown that the peculiar properties of relaxor ferroelectrics are due to the presence of a multidomain state (Takenaka *et al.*, 2017). The simulated multidomain structure of relaxor ferroelectrics have been

Fig. 6 Dielectric permittivity versus temperature at different frequencies for a relaxor ferroelectric. The arrows show the increasing of measurement frequencies. Modified from Cordero, F., Corti, M., Craciun, F., *et al.*, 2005. Polar and nonpolar atomic motions in the relaxor ferroelectric PLZT from dielectric, anelastic and NMR relaxation. *Phys. Rev. B* 71, 094112-1-9.

compared with experimental diffuse scattering results. More specifically, MDS of $72 \times 72 \times 72$ unit cells of 0.75PMN–0.25 PT has been made between 100 and 700 K, and the diffuse scattering intensity, which is related to the deviation of local structure from the average structure, was obtained. From the analyses of the angles between the Pb–O₁₂ dipoles along the $\langle 100 \rangle$, $\langle 110 \rangle$, and $\langle 111 \rangle$ directions, it has been found that the relaxor state consists in a multidomain disordered ferroelectric state with a very small domain size (2–10 nm) and with various low-angle domain walls separating small polar domains, without a nonpolar matrix. It has been shown that the peculiar butterfly shape of diffuse scattering patterns is a characteristic of this multidomain state. Conceptual pictures of the structural changes through the phase transitions and corresponding computed diffuse scattering patterns have been obtained. The successive phases, starting from high temperature, have been found to be: Paraelectric phase ($T > T_b$), relaxor phase with fluctuating domains ($T^* < T < T_b$), relaxor phase with static and dynamic domains ($T_f < T < T^*$), and frozen phase with static domains with very slow dynamics ($T < T_f$). An important feature is that the surrounding matrix is itself polar, but with different correlations and different dynamics (Takenaka *et al.*, 2017).

By analyzing the influence of the local environment on the Pb displacements, using the distribution of time-delay-averaged angle autocorrelation, it was found that in various environments (i.e., in subgroups with different B-cation nearest neighbors) the correlations show different dynamics and develop at different temperature (Takenaka *et al.*, 2017). In the case of PMN–PT, the Mg-rich sites decouple polarization fluctuations of the neighboring Pb sites and are therefore the cause of the small domain size. This is due to the small off-center displacement of Mg²⁺ ions arising from their large size and simple metal electronic structure. This result clearly points to a common microscopic cause of small domain size and relaxor behavior in many apparently different ferroelectric relaxors, residing in the different environment of the ferroelectric ions due to doping or due to the casual distribution of the ions.

The presence of small nanodomains in relaxors has been shown to lead to Kohlrausch–Williams–Watts dielectric relaxation and to Vogel–Fulcher type behavior for the dielectric response of relaxors (Chamberlin, 2014).

Moreover, the peculiar microstructure of the relaxor phase, which involves a high density of domain walls and the presence of a mixture of ferroelectric and paraelectric-like unit cells (Takenaka *et al.*, 2017), favors polarization rotation and gives rise to high piezoelectric response.

Applications

The main applications of the ferroelectric ceramics presented here are based on their high piezoelectric response. Indeed, as underlined in Cross and Heywang (2008), the piezoelectricity market worldwide involves a turnover of billions of dollars, covering a wide range of applications, from information and communications, to industrial automation, medical diagnostics, defense industries, etc.

The field of piezoelectric devices was boosted by the development of ferroelectric ceramics with enhanced piezoelectric properties. On the other hand, the increased market has stimulated the search for new or improved functional ceramics.

As pointed out in Cross and Heywang (2008), the number of installed piezoelectric samples in some industrial fields counts several billions, for example, in automotive applications, buzzer devices, ultrasonic imaging, high power transducers and shock wave generation, printers, ignition devices, etc.

A comprehensive list of application fields of piezoelectric ceramics can be found in [Cross and Heywang \(2008\)](#). In the category of sound and ultrasound devices, the buzzers have reached a market of several billions. They are made of ceramic tapes of soft PZT and are used for sonic alerts. Microphones and speakers based on ceramic tapes of soft PZT or PZT thin films are used in telephones, blood pressure measuring devices, etc. Ultrasonic imaging devices based on diced plates of soft PZT or PZT thin films are used in medical diagnostics. Hydroponic devices are based on PZT ceramics and composites and are used as sources or detectors for sound location.

High power transducers and shock wave generation devices have also reached a market of several billions. They are based on ceramic disks of hard PZT and are used in machining, ultrasound cleaning, lithotripsy, etc. Other applications are for atomizers made of ceramic disks of soft PZT used for oil atomizers, humidifiers, and aerosols. Air ultrasound devices made from ceramic disks of soft PZT are used for distance meters, intrusion alarms, etc.

Other applications are in the category of actuators and motors. For printers the market reached billions of installed samples ([Cross and Heywang, 2008](#)), bars, tubes or multilayer ceramics of soft PZT are used for needle drives and ink jets. For motors and transformers, rings, plates of hard PZT or soft PZT, multilayer ceramics, or even PZT thin films are used for miniaturized, compact motors and transformers.

Also bimorph actuators based on PZT multilayer ceramics are used for microelectromechanical systems like micropumps and Braille devices. Multilayer actuators based on multilayer stacks of soft PZT are used for fine positioning and optics. Injection systems based on multilayer stacks of soft PZT are employed for automotive fuel valves.

In the category of sensors, acceleration sensors based on rings or plates of soft PZT are used for automotive and medical devices. Another application field where the market has reached several billions devices is that of ignition devices based on hard PZT cylinders. These are used for gas and fuel ignition.

Adaptive devices based on various shape samples or multilayer stacks of soft PZT are used for active noise and vibration cancellation, adaptive control, etc. ([Cross and Heywang, 2008](#)).

The market for piezoelectric materials is continuously expanding, in line also with new tendencies toward the transfer and implementation of piezoelectric devices at micro- and nanoscale.

Different requirements are imposed on the employed piezoelectric ceramics used in different applications. For example, for vibrator applications, hard piezoelectric ceramics with high mechanical quality factor are preferred.

Different requirements are also imposed on the shape and dimensions of active elements used for speakers or buzzers in the domain of audible frequencies. Specific elements like unimorphs consisting of a piezoceramic plate bonded with a metallic shim, or bimorphs consisting of two piezoceramic plates bonded together, have been employed. The advantages of the piezoelectric buzzer over electromagnetic devices include high electric power efficiency and compact size. Piezoelectric speakers can have very small dimensions and weight (about 0.7 mm thickness and 0.4 g weight), with very low power consumption ([Uchino, 2017](#)).

Also in the field of ultrasonic transducers, piezoelectric ceramics show superior efficiency and have minor size than magnetostrictive materials. For these applications, piezoelectric materials with high piezoelectric constants but also high mechanical quality factor are preferred, since high power generation without heating is desired ([Uchino, 2017](#)). These transducers are widely used in sonars, ultrasonic washers, ultrasonic scanning detectors for diagnosis and therapy/surgery clinical applications, non-destructive testing, microphones, etc.

Ultrasonic imaging is one of the most developed application fields employing piezoelectric transducers, and it is also largely known due to its clinical applications ([Uchino, 2017](#)). For these imaging applications, ultrasonic transducers work for converting the electrical signal into an acoustic pulse and for converting the received echo back into an electric signal, which is registered, elaborated, and translated into useful images. The received mechanical signal carries information about the density and elasticity of the tissues. When carried out in real time, the ultrasonic imaging process allows following of moving bodies, like heart movement. The advantages of the ultrasound imaging technique over X-ray techniques is obviously related to the safety of employment.

For this type of ultrasonic transducer, besides high electromechanical coupling coefficient, high anisotropy is also desired, that is, a high ratio of the longitudinal mode coupling to the planar mode coupling, together with a large dielectric constant, which enables good electrical impedance match to the system ([Uchino, 2017](#)). Many imaging systems use multiple element array transducers. This structure allows focusing to various penetration depths, by the individual driving of the various elements and use of phase delays.

Other piezoelectric applications include sonochemistry, based on the cavitation effect in liquids. This effect is employed to transform toxic liquids into nontoxic components at ambient temperature.

Ultrasonic technology has been implemented also for transdermal drug delivery, for example, in systems for "needle-free" insulin injection ([Uchino, 2017](#)).

Other applications include piezoelectric transformers. The operation principle of a piezoelectric transformer consists of the input voltage amplification through the vibration energy transfer. The voltage rise ratio is proportional to the length/thickness ratio for a piezoceramic plate formed by a section poled on thickness and another section poled on length ([Uchino, 2017](#)). Piezoelectric transformer advantages over normal electrical transformers include smaller size and the lower noise. Multilayer-type transformers have been also developed in order to increase the voltage rise ratio. Moreover, by inverting the role of the different sections, voltage can also be decreased. This type of transformer has been developed for mobile phones and laptop computers.

Another field where piezoelectric ceramics are largely employed is in piezoelectric actuators such as high precision positioners, miniaturized ultrasonic motors, and vibration dampers. Indeed modern automation equipment requiring ultraprecise positioning

systems in the range of fractions of micrometers and minimotors smaller than 1 cm imposed the unrivaled use of piezoelectric actuators and motors, cutting out the conventional electromagnetic systems (Uchino, 2017).

Piezoelectric pulse drive motors have been also developed. They work in an on/off switching mode and are mainly used in inkjet printers. The pulse drive motor requires a low permittivity material with a quick response, thus soft PZT piezoelectric ceramics are employed.

Other important industrial applications of piezoelectric ceramics are ultrasonic motors. Electromagnetic motors cannot compete with ultrasonic motors at small size level. Indeed electromagnetic motors smaller than 1 cm have very low energy efficiency <1%. Therefore, ultrasonic motors based on piezoceramics, with high efficiency that is also independent of size, are unrivaled in the field of micromotors. The development of this field has been boosted by the urgent demand in the industry of semiconductors for very precise positioners.

Micromotors employing standing-wave type vibrations have also been developed. In this type of motor, the piezoelectric driver forms a resonating structure with another vibratory piece, when properly tuned. The efficiency of this motor can reach values as high as 90% (Uchino, 2017).

Piezoelectric ceramics are employed also in energy harvesting devices, which can recover energy from, e.g., car engines. The energy harvesting devices based on metal–ceramic composite transducers succeed to generate continuously 1 W under a force of a few tens of N and frequency of 100 Hz (Kim *et al.*, 2005). The device can perform two tasks at the same time: Vibration damping and energy harvesting.

Another important application of piezoelectric ceramics is in the field of common rail diesel injectors. The first vehicles equipped with these injectors entered into production in 2000 (Mock and Lubitz, 2008). In the first generation of piezoelectric injectors, a servohydraulic mechanism was employed to move the nozzle. Instead, for gasoline high pressure direct injectors the nozzle is actuated by a piezoactuator. The series production for this injector was begun in 2006 (Mock and Lubitz, 2008).

The use of piezoelectric ceramics in motor injection systems imposes some requirements on their properties, due to the demanding functional conditions: Drive voltage up to 200 V, large piezoelectric extension (40 μm), operating temperatures from -40°C to 160°C , a minimum life time of 10^9 cycles, etc. To fulfill these requirements piezoceramic prismatic stacks have been fabricated by multilayer technology. A few hundred ceramic sheets of about 100 μm have been sandwiched between AgPd thin electrodes with alternate polarity (Mock and Lubitz, 2008). A high effective piezoelectric coefficient of about 750 pm V^{-1} at 2 kV mm^{-1} is required. Soft PZT ceramics doped with rare earth elements at the A-site and/or Nb at the B-site are employed. Besides high piezoelectric response, these materials show also higher Curie temperature.

Conclusions

The field of functional ceramics with ferro/antiferroelectric, relaxor, and piezoelectric properties is continuously expanding, boosted by the increasing market demand. Here, we have introduced some general concepts regarding dielectric materials. The phenomenological treatment of piezoelectrics has been discussed. The effect of crystal symmetry on the reduction of the number of independent piezoelectric moduli in piezoelectric materials has been considered.

Phase transitions in ferroelectrics and antiferroelectrics have been discussed in terms of the phenomenological theory of Landau. A brief presentation of some microscopic models of ferroelectricity and first-principle methods has been given.

A discussion of the effective properties of ferroelectric ceramics has been given. It has been shown that in a first approximation they can be obtained by averaging over the various orientations of the domains in the crystallites. Nonlinear properties of ferroelectric ceramics have been introduced.

General characteristics and most recent models regarding the origin, structure, and behavior of nanopolar regions in relaxor ferroelectrics have been discussed.

The main applications of the ferroelectric ceramics based mainly on the piezoelectric properties have been presented. It has been underlined that the piezoelectricity market worldwide involves already a turnover of billions of dollars, covering a wide range of applications.

Moreover, the market for piezoelectric ceramics is continuously expanding, also in line with the new tendencies toward the transfer and implementation of piezoelectric devices at micro- and nanoscale.

Introduction

One of the most challenging tasks in material science is the need to produce tailored materials with advanced characteristics for various types of modern applications in wide areas, in order to meet present and future challenges concerning the multifunctionality, mechanical and thermal stability, but also reliability, low cost, low energy budget and sustainability. The traditional trial-and-error loops during the researching and development of new materials can be substantially reduced by using modeling and simulation tools, which are able to propose predictions concerning smart materials, new structural arrangements and conditions to obtain exceptional functional properties. Computer-aided modeling is considered the most recent paradigm of scientific discovery, by completing and supporting the theoretical and experimental investigation approach. Recent advances in numerical methods, coupled with an outstanding increase of computational resources, have led to a tremendous progress in the development and integration of modeling tools to the study of a wide range of materials systems and properties (Gates and Hinkley, 2003; Thornton and Asta, 2005). Therefore, modeling and simulation are currently finding increasing applications not only in basic science concerning the fundamental aspects in materials science, but also in the industrial need of design and optimization of new materials for specific applicative demands, by strongly reducing the time and cost-intensive effort dedicated to the synthesis and characterization of materials.

The continuous trend of technological miniaturization, leading to downscaling of materials, combined with the possibility to experimentally probe the properties at various time- and length-scales, stimulated a growing interest in theoretically describing the observed properties. In this sense, the most recent trend is to integrate the numerical methods in the frame of multiscale modeling, with the final goal to predict the functional properties across relevant length- and time-scales. As schematically indicated in Fig. 1, the main theoretical approaches used to describe materials are (Yip and Short, 2013; Lubber, 2019):

- (1) *Ab-initio* (first principles) and atomistic models, which describe systems at atomic scale taking into account the electronic structure by solving the Schrödinger equation within some certain approximations without involving any empirical inputs and are able to predict real behavior of materials under controlled environment (e.g., ground state properties);
- (2) Molecular dynamics, which is a numerical method dedicated to solve the dynamic Newton equation and simulate the physical movement of atoms and molecules that are subjected to reciprocal interactions for a fixed period of time due to specific mechanical or interatomic forces (treated in quantum or classical approximation);
- (3) Mesoscale discrete models (Monte-Carlo, Ising, Potts, Heisenberg approaches) were developed for spin systems evolving with certain probability due to random variables and are able to describe some macroscopic properties or phenomena (switching in ferromagnetic or ferroelectric materials, grain growth, sintering, statistical economics, social systems, etc.) by considering discrete interactions between single elements of the system;
- (4) Micro-/meso-/macroscale models, either discrete (applied to coarser individual entities like crystallites or ceramic grains, layers, etc.) or continuous, imply a range of homogeneity at a certain scale level. Therefore, the system consists of a number of such repeating unit cells or representative volume elements (inspired from the real micro-/meso-/macroscale structure) whose properties and interactions are derived from lower scale modeling outputs or experiments and can predict average effective properties of inhomogeneous materials (ceramics, metals, composites) in a large range of length-scales. Among them, the effective field models consider the appropriate degree of freedom to describe phenomena at a given length-scale (or energy scale), while ignoring substructure and degrees of freedom at shorter distances (or at high energies). Finite differences methods are numerical tools used to solve differential equations describing materials by approximating the local derivative by finite differences. More effective, finite elements method (FEM) is a numerical tool for solving problems in physics, material science and engineering (e.g. electromagnetic field distributions, currents and heat transfer, fluid flow, etc.) which are mathematically described by complex differential equations. The method is based on the system discretization in a large number of small components (finite elements), for which simpler differential equations with specific boundary conditions are numerically solved and then the properties of the entire system are derived. FEM provides the closest description of inhomogeneous systems as multi-phase materials, composites, etc., in relationship with their microstructure and is a very useful tool to describe electrical, magnetic, thermomechanical, electromechanical, optical processes, etc. Macro-scale models are particularly useful for describing the material's behavior and predicting its response in real structures or devices. Macroscopic properties are usually described by empirical or semi-empirical physical models.

As reviewed in Ref. Iuga (2007), quantum mechanical description is necessary to characterize the electrons and collective behavior of atoms in the material at nanoscale, while at engineering scale, local gradients (of temperature, stress, fields) may be the main driving forces controlling the local materials characteristics. At intermediate scales, defects (charged defects, grain boundaries

Fig. 1 Different types of models corresponding to various time and length-scales.

in ceramics, mechanical defects, dislocations, layers either localized or extended in scale) will control the microscopic (at the level of tens-hundreds of micrometers) functional properties which in turn, will ultimately determine the continuum macroscale properties.

Polycrystalline ceramics are synthetic nonmetallic inorganic compact aggregates formed by a large number of grains (single- or polycrystalline) of various shapes, size and orientations, determined by the chemical composition and processing parameters. Advanced ceramics have been mostly developed in the last four decades for high-tech specific applications, like structural, mechanical, thermal, electric or magnetic properties. Among them, electroceramics are advanced materials with a broad range of applications as insulators, inductors, superconductors, microwave dielectric resonators, electrooptic, piezo- and pyroelectric transducers and many others, whose development shows an exceptional development related both to the production of new materials and structures as well as on their miniaturization and integration in microelectronic circuits. Like in case of other materials, the functional properties of electroceramic materials depend upon their composition and nano/microstructure. But more than that, what is of highest interest is that their properties can be tuned by external stimulus such as field, temperature, stress, irradiation, chemical composition of the surrounding medium, etc. and often more than one property is present in the same structure, i.e., they show multifunctional character. Therefore, many electroceramics are active materials, whose properties are controllable by external inputs. Among the wide class of smart multifunctional materials, ferroelectric oxides brought outstanding contributions in various technological applications and in particular, in microelectronics (Xu, 1991; Bell, 2008; Bain and Chand, 2017). Their greatest engineering impact is closely related to the progressive growing knowledge in the synthesis of micro/nanostructured oxide particles, to the defect chemistry, and to the control of ceramic processing and sintering mechanisms. The most important ferroelectric oxides employed in microelectronics applications are complex oxides as BaTiO_3 -based ceramics, SrTiO_3 , $\text{Pb}(\text{Zr,Ti})\text{O}_3$ family, PbTiO_3 and its compounds, relaxors as $\text{Pb}(\text{Mg}_{1/3}\text{Nb}_{2/3})\text{O}_3$ or $\text{Pb}(\text{Zn}_{1/3}\text{Nb}_{2/3})\text{O}_3$, LiNbO_3 or BiFeO_3 , in various structures as ceramics, thick or thin films, multilayers or complex miniaturized integrated structures.

The microstructure of ceramics is characterized by grains, grains boundaries, porosity and glass or secondary phases. To simulate the macroscopic functional properties, it is necessary firstly to build a representative geometry that incorporates the overall features of the real structures, like shape and grain size (and size distribution), pore volume fraction and their geometry and distribution, volume fraction of different phases in composites and their interconnectivity, interfaces between different phases, grain boundary thickness, etc. (Iuga, 2007; Lubner, 2019). According to the scale of modeling and for the accuracy of predicted results, inputs and validation for the models either based on experimental data or from other simulation results (as for example from first principles calculations) are necessary.

In the following, some of the main modeling approaches used to investigate and describe the properties of polycrystalline electroceramics, together with a few case studies are presented.

Models for Describing the Sintering Process and Microstructure Evolution in Electroceramics

General Aspects of Sintering

Besides the composition and phase symmetry, the material microstructure plays an important role in understanding and controlling the macroscopic responses of real materials. More specifically, for electroceramics, information about the nanoscale properties (e.g., ferroelectric domain structure, charge point defects, impurities) and microstructures (ceramic grain size and shape, texturing, nature, thickness and properties of grain boundaries, extended planar defects as dislocations, or volume defects, pores: size, shape and interconnectivity) are necessary to derive their physical and chemical macroscopic properties. Therefore, a good understanding of the microstructure evolution during the preparation steps (powder synthesis, pressing, sintering) is essential for the properties' optimization. Besides the microscopical experimental observation of ceramics, modeling the microstructures is an essential step for understanding and predicting the functional properties.

Predicting powder densification during sintering. *Journal of the European Ceramic Society* 38 (4), 1736–1741. doi:10.1016/j.jeurceramsoc.2017.10.020, with permission.

Sintering process represents the conversion of pressed powders (green body) into a dense ceramic with controlled density and microstructure, realized by heating at high temperatures, below the melting point (Gómez and Hotza, 2018). This process takes place by the transport of material to or around the pores (lattice diffusion, grain boundary diffusion, viscous flow) under appropriate conditions of temperature, pressure and environment under the driving force related to the tendency of system to decrease its total surface and interface energy (Bordia *et al.*, 2017; Gómez and Hotza, 2018). Particle bonding, density increase and grain coarsening processes with various weights, take place during the classical sintering stages (Fig. 2).

Examples of Models Aimed to Describe the Sintering Stages and to Generate Ceramic Microstructures

Multiple efforts were dedicated to studies of sintering and microstructural evolution aimed to understand the thermodynamics and to develop appropriate models to quantify the grain growth kinetics, by considering the interplay between powder particle shape and size distribution, impurities and lattice distortions in the green body and the diffusion process, particle rearrangements, chemical reactions at interfaces, etc. Already in the middle of the 20th century the first classical description of grain growth and microstructure evolution during sintering have been proposed for the solid-state sintering, based on the idea of material flow and vacancy flow, both leading to the reduction of the free surface energy (Frenkel, 1945; Bordia *et al.*, 2017). In the next decades, various models describing the initial (Coble, 1961; Coblenz *et al.*, 1980), intermediate (Johnson, 1970; Zhao and Harmer, 1991) and final (Zhao and Harmer, 1991; Kang and Jung, 2004) stage of classical sintering were proposed. Starting from the same powder microstructure, various types of microstructures (grain size and shape, pore morphology and distribution) were generated by recent phase field complex simulations when considering the effect of anisotropic properties of powders (e.g., direction-dependent interface diffusion anisotropy, and grain orientation dependent grain boundary energy anisotropy) (Biswas *et al.*, 2018). One example showing the role of grain boundary anisotropy on the final microstructures generated by phase field simulations is presented in Fig. 3 (Biswas *et al.*, 2018).

Recently, Raether *et al.* (2019) proposed a new integrated microstructure continuous model on solid state sintering which provides highly realistic ceramic microstructures. This approach requires reasonable computer resources and show small statistical variations and includes the most important aspects of current computational microstructural models as: interface energy controlled local equilibrium structures, randomness of diffusion processes, and particle rearrangement. Fig. 4 illustrates such a simulated 3D microstructural evolution during the initial, intermediate and final stage of sintering (Raether *et al.*, 2019).

Due to the difference in the chemical potential of the atoms under curved surfaces, the atoms are transported to the particle neck entailing the redistribution of material on the surface of particles without densification (bonding), and from the particle surfaces or grain boundaries, which induces densification (shrinkage) additionally to bonding (Frenkel, 1945; Raether *et al.*, 2019). The microstructures of the intermediate and final stages of sintering are determined by phenomena as grain-boundary diffusion and lattice diffusion from the grain boundary to the pore surface which were described by kinetic (transport) equations, in which pore-grain boundary interactions and their mobilities were also considered (Frenkel, 1945; Du *et al.*, 2018; Raether *et al.*, 2019).

Not only the formation of residual porosity inherent in electroceramics, but mostly the desired porosity for specific applications is important to be described by models in which to consider the complex processes related to the variety of interactions between pores and grains. For understanding the processing parameters affecting the level and distribution of pores, the pore deformation and grain boundary migration during sintering of porous ceramics were simulated in a recent study by phase-field methods in which the variety of diffusion processes during sintering were considered (Du *et al.*, 2018; Rehn *et al.*, 2019). Therefore, pores of different shapes and sizes were considered in the simulations to investigate the grain boundary migration and pore deformations during the grain growth. Simulations show that the porous microstructure is strongly affected by the contacting

mode between pore surface and grain boundaries (Fig. 5), which is in good agreement with experimental observations of real porous ceramic microstructures.

Computational-aided design of microstructures was realized by phase field simulation for textured ferroelectric ceramics, as exemplified in Fig. 6 in which the role of template seeds configuration and corresponding grain growth for a given template composition is shown (Zhang and Liu, 2019), and a plethora of numerical approaches have been developed for generating microstructures in different types of heterogeneous composites (Cheng *et al.*, 2009; Bargmann *et al.*, 2018). An excellent overview of these methods is presented in Ref. Bargmann *et al.* (2018), in which numerical methods to describe realistic microstructures of non-porous materials as polycrystals (grains or lamellar), bi-continuous composites, matrix-inclusion composites (particle reinforced or lamellar reinforced) and porous systems as agglomerates (cellular, dilute voids), fabrics (woven and non-woven) and aggregates are reviewed.

Together with the development of new sintering techniques implemented to improve the densification, and/or suppress the grain growth (like pressure-assisted sintering, microwave sintering, two- or multi-step sintering, and electric field assisted sintering e.g., Spark Plasma Sintering SPS, etc.) (Munir *et al.*, 2006), models for specific processes involved in such sintering techniques were also proposed. Some of them, in particular ones involving highly inhomogeneous systems and describing strongly non-equilibrium processes (e.g., SPS) are still a matter of debate. More specifically, the models describing SPS processes should interconnect at least three different physical processes: the density of the sample determines the local field distribution and electrical behavior, which in turns controls the local temperature distribution who will finally govern the densification rate (Du *et al.*, 2018; Raether *et al.*, 2019; Rehn *et al.*, 2019), while simulations of the processes involved in microwave sintering requires coupling of at least three physical coupled phenomena: stationary electromagnetic waves in cavity and the local field distributions in the sample, heat transfer, and ceramic densification (Bimboim and Carmel, 1999; Bouvard *et al.*, 2010; Rybakov *et al.*, 2013).

Fig. 6 Left: simulation of sintering of textured ceramics by using template seeds: grain growth at various sintering times for two types of initial template configurations. Right: microstructural evolution for a template fraction of 18.7%. Adapted from Zhang, Y., Liu, L., 2019. Computational design of microstructures of textured ferroelectric ceramics by phase field simulation. Computational Materials Science 159, 24–31. doi:10.1016/j.commatsci.2018.11.051, with permission.

The peculiar aspects of the processes involved in obtaining specific types of engineered microstructures in textured ceramics by template growth (Zhang and Liu, 2019) were also described by phase field simulations (Zhou et al., 2017b,a) and the recent interest in additive manufacturing attracted interest in developing models to produce realistic numerical microstructures (Abdeljawad et al., 2019).

Besides the physics-based models targeting simulation of the physical processes responsible for the microstructure formation and evolution (as the sintering models mentioned before) there are purely geometrical methods solely mimicking the morphology while ignoring the physical basis of the microstructure formation process. It is worth to note that together with numerically generated microstructures, real 3D ceramic microstructures can be reconstructed through experimental characterization of microstructures either by using serial sectioning techniques or based on transmissive radiation, i.e., micro-tomography (Elissalde et al., 2015; Lesseur et al., 2015; Bargmann et al., 2018). However, accurately reconstruction of 3D microstructures for a significant sample volume requires acquisition, storage and processing of a huge amount of data, so that numerically generated realistic microstructures are still applied as a good basis for modeling the functional properties of electroceramic materials.

Models for Describing the Functional Properties of Electroceramics

Effective Dielectric Properties in Inhomogeneous Ceramics: Composites and Porous Ceramics

Theoretical prediction of effective properties for multiphase materials is a very important issue not only for analyzing and optimization of material functional properties, but also for design of new material and structures. Effective medium approximations (EMA) are mesoscale approaches (discrete or continuum-type) proposing analytical or theoretical calculations of the

Fig. 7 Real part of the effective permittivity vs. volume filling fraction of nickel ferrite-Nb-doped PZT ceramic composites together with EMA approximations (Maxwell-Garnett, Lichtenecker and Bruggeman) and results of FEM calculations. Reprinted from Ciomaga, C.E., *et al.*, 2012. Low field permittivity of ferroelectric-ferrite ceramic composites: Experiment and modeling. *Journal of Applied Physics* 112 (9), 094103. doi:10.1063/1.4764037, with permission.

material properties in composites use an averaging of the multiple values of the composite material properties and derive approximations for the effective properties. All these EMA approaches consider the composite material to be homogeneous at macro-scale but locally inhomogeneous, being described by local relevant physical parameters and constitutive laws with boundary conditions. The dielectric properties of composites are defined by the permittivity derived from the local atomic/molecular structure of the individual constituents, but also by the composite structure. If the composite consists of two or more homogenous materials and there are boundaries between these material phases, then there are polarization mechanisms in the scale of inhomogeneities in addition to polarization mechanisms related to individual atoms and molecules. If the scale of inhomogeneities in the mixture is much smaller than the wavelength field inside the mixture (i.e., the electromagnetic field cannot “see” the inhomogeneities in the material), one can define the effective permittivity for the material. There are many classical mixing equations (e.g., Bruggeman, Maxwell-Garnett, Lichtenecker, etc.) (Sihvola, 1999; Wang and Pan, 2008) and their usefulness to predict dielectric properties of realistic di-phase composites is limited to some specific microstructures and in limited ranges of compositions. More appropriate description for realistic microstructures is provided by using local scale field calculations (Elissalde *et al.*, 2015; Lesseur *et al.*, 2015) or finite element models (FEM), as for example shown in the description of permittivity in ferroelectric-ferrite composites with different types of phase arrangement (Ciomaga *et al.*, 2012; Guzu *et al.*, 2019) or in other types of dielectric-based composites (Brosseau, 2006; Ciomaga *et al.*, 2014). For example, for nickel ferrite-PZTN ceramics, the FEM calculations provided the best approximation for describing effective dielectric constant in all the range of compositions with respect to EMA models (Fig. 7, (Ciomaga *et al.*, 2012)) because realistic microstructures were employed for calculations.

The FEM method and other types of local potential calculations (as finite difference methods or other approaches for solving Poisson local equations in discrete elements) are very useful tools to derive anisotropic dielectric properties in dielectric-based ceramic composites (see Fig. 8 (Lesseur *et al.*, 2015)) and to design ferroelectric-linear dielectric composite ceramics for tunable applications, for which a non-linear permittivity dependence on the local field is proposed for performing calculations. Tunability, i.e., the field variation of permittivity $\epsilon(E)$ is a typical non-linear dielectric property characteristic of ferroelectrics. However, ferroelectrics also possess high permittivity above 1000, while for tunability applications a permittivity of hundreds would be required (Tagantsev *et al.*, 2003). Therefore, the “dilution” with a non-linear low permittivity dielectric constant was a generally accepted approach to produce tunable composites with desired characteristics (Astafiev *et al.*, 2003). However, usually the tunability was also lost or strongly diminished by the addition of such non-linear dielectric phase. In the last few years it was clearly demonstrated by modeling that only a few specific configurations in such composites provide the required reduction of permittivity while preserving a high tunability (Padurariu *et al.*, 2016, 2017). As linear dielectric, besides other low permittivity inclusions, air pore inclusions are most effective to induce electric field fringes and to concentrate the electric field in some specific regions of the material determining a significant tunability response. However, the pore size, shape and distribution should be well controlled during the ceramic processing, because some local configurations give rise to a diminished response with respect to one of the pure ferroelectric material (Padurariu *et al.*, 2016, 2017).

Porosity is inherent to ceramic processing and usually is detrimental for the functional properties of ceramics. However, for some specific types of pore microstructures, the properties can be enhanced due to the favorable pore configurations allowing a field enhancement in some desired material regions (so called “hot spots”). For example, the role of variable amounts of anisotropic pores on the dielectric properties of PZT ceramics was investigated and the importance of pore’s shape factor was estimated by calculations (Fig. 9 (Olariu *et al.*, 2013)). It was demonstrated that the fastest decrease of permittivity versus porosity is realized for elongated pores rather than for spherical pores inclusions (Olariu *et al.*, 2013). The same trend was experimentally shown for (Ba,Sr)TiO₃ ceramics with lamellar porosity, which was also described by FEM calculations (Stanculescu *et al.*, 2015).

Fig. 8 Permittivity of BaSrTiO₃ ceramic composites with MgO anisotropic inclusions and calculations using real microstructures determined by XRD micro-tomography. Reprinted from Lesseur, J., *et al.*, 2015. 3D mapping of anisotropic ferroelectric/dielectric composites. *Journal of the European Ceramic Society* 35 (1), 337–345. doi:10.1016/j.jeurceramsoc.2014.07.032, with permission.

Fig. 9 Effective permittivity vs. porosity for different aspect ratios and experimental permittivity data for parallel and perpendicular configurations. Reprinted from Olariu, C.S., *et al.*, 2013. Investigation of low field dielectric properties of anisotropic porous Pb(Zr,Ti)O₃ ceramics: experiment and modeling. *Journal of Applied Physics* 114 (21), doi:10.1063/1.4837616, with permission.

Even the calculations using 2D microstructures derived from SEM imaging provide relevant qualitative results concerning the permittivity, tunability and polarization responses in ferroelectric-linear dielectric composites, it is highly important to note that only the 3D FEM modeling is the correct approach for predicting correct responses in materials with realistic microstructures (Lesseur *et al.*, 2015; Padurariu and Mitoseriu, 2016a). As clearly demonstrated in Ref. (Padurariu and Mitoseriu, 2016a), the field distributions for 2D and 3D models generated for randomly distributed phases are different (Fig. 10 – Left) and this reflects mostly on the effective nonlinear dielectric properties. Namely, the 2D approach over-estimates the tunability, providing tunability values even higher than in pure ferroelectric material at low amounts of the linear dielectric filler in ferroelectric-linear dielectric composites, and strongly under-estimates the tunability for concentrations of the linear dielectric phase above 70% (Fig. 10 – Right) (Padurariu and Mitoseriu, 2016a). Therefore, the limits of such approaches should be always critically discussed.

Fig. 10 Simulated 2D and 3D local field distributions for $(\text{Ba,Sr})\text{TiO}_3$ -linear dielectric composite ceramic (Left) and the corresponding computed permittivity and tunability (Right) for various concentrations of the linear dielectric phase. Comment on "The impact of composite effect on dielectric constant and tunability in ferroelectric-dielectric system". *Journal of the American Ceramic Society* 99 (11), 3816–3817. doi:10.1111/jace.14421, with permission.

Description of the Role of Defects, Interfaces, Grain Boundaries and Size Effects on the Electrical Properties of Ceramics

Defects

Defects are always present in real materials and it is necessary to understand how they affect their macroscopic (functional) properties and performances. In particular, the presence of charged defects like vacancies or substitutional ions may deteriorate a property, like for example scattering by charged defects which is known to reduce the electron mobility (Lischner, 2019). Some charged defects may also enhance properties or even introduce completely new functionality, this allowing the rational design of defect-based functionality (so called "defect engineering"), like for example in the silicon-based conventional semiconductor technology generated by doped materials. Modeling charged impurities is particularly challenging because their properties are determined by physical-chemical processes taking place on multiple length scales: charge transfer is determined by the short-ranged overlap of frontier orbitals, the screened potential of the charged defects is affected by the long-ranged dielectric response bulk material and the effective dielectric response is determined by meso- and macroscale electrical material characteristics (permittivity, conductivity). To capture such a complex interplay, multiscale theories combining first principles methods with mesoscale and coarse-grained approaches, such as interacting continuum models have been proposed (Homer, 2019; Lischner, 2019).

Grain boundaries

The topic of interface-controlled electroceramics whose electrical properties are predominantly determined by their grain boundaries is of enormous technological importance as well as high scientific interest. Their peculiar non-linear transport properties are caused by space charge layers owing to the formation of double Schottky barriers at the grain boundaries. The formation of such a charged region at the grain boundary region is a result of the discontinuity of the ionic lattice properties, Fermi level mismatch and of the difference in the adsorption (or segregation) of charged defects at the interfaces. In pure materials, intrinsic electric boundary charge arises from localized surface states for charged ions and for electrons and charged vacancies with energies different from the bulk values. The resulting boundary compositions, stoichiometry, and associated electric charges depend on the composition (purity) and processing and sintering parameters. Generally, a random grain boundary contains steps and kinks which can act as sources and sinks for ion vacancies. Therefore, the requirement for charge neutrality into the bulk gives rise to a boundary charge and an associated space charge region. When doped with aliovalent ions in solid solutions, the vacancy concentrations in the bulk and the electric charge on the boundary are affected, while heterovalent substitutions produce depleted regions at the grain boundaries and Schottky barriers (when an important difference between the bulk and grain boundary conductivity appears as result of dopants segregation at grain boundaries) (Chen and Yang, 2011; Preis and Sitte, 2015; Uriz *et al.*, 2018). Defect chemical model-based approaches (Landau lattice ferroelectric models combined with Schottky double barrier model) describing the combined ferroelectric-semiconductor character of n - doped oxides as BaTiO_3 and his solid solutions were proposed in order to derive the bulk and grain boundary resistivity as a function of temperature, dc bias, and other parameters as doping level, oxygen partial pressure or type of ferroelectric lattice or in p-doped oxides (as SrTiO_3) for the simulation of charge transport across grain boundaries under dc load (Höbling and Waser, 2002). Grain boundary engineered ceramics are essential for varistors applications (zinc oxide-based compositions or positive temperature coefficient resistive materials (PTCR) such as n-doped semiconductor BaTiO_3 ceramics), for giant permittivity materials as ceramics with semiconductor grains and high-insulating grain boundary layers or in ferrite ceramics for which the impedance and magnetic properties are strongly dependent on the nature and properties of grain boundaries.

The different electrical properties of grain boundaries with respect to their cores in non-doped ferroelectric ceramics have been usually described by using brick-layer models, as reviewed in Refs. Emelyanov *et al.* (2002); Petzelt (2010). In such ceramics, the grains have a core-shell structure (Fig. 11), with grain boundaries of variable thickness, which are considered as non-ferroelectric ("dead-layer" region) with a field-independent low-permittivity which fully isolate the ferroelectric core region (grain bulk).

Fig. 11 “Brick layer” model for ferroelectric ceramics: linear dielectric grain boundary, ferroelectric grain core.

Therefore, any ceramic material may be described as a composite and effective field models (Emelyanov *et al.*, 2002; Polotai *et al.*, 2003; Petzelt, 2010) or numerical approaches (Padurariu *et al.*, 2012; Padurariu and Mitoseriu, 2016b; Wu *et al.*, 2016) can be employed to compute their dielectric effective properties. An important observation derived by such numerical calculations is the field inhomogeneity inside the ceramic material, even in plan-parallel capacitor configuration, which only recently started to be considered in literature.

The impact of grain boundaries on the macroscopic properties of ferroelectric ceramics is enhanced when reducing their grain size down to nanoscale (tenths of nanometers), due to the increasing weight of a large amount of grain boundaries with respect to the contribution of grain cores. Practically, all the electrical properties of nanostructured ceramics are determined to a large extent by their large number of grain boundaries. This “dilution effect” can explain the strong reduction of the effective permittivity towards the complete disappearance of the ferro-para phase transition and decrease of tunability towards a permittivity versus field linearization when reducing grain size (scale-dependent extrinsic properties). The presence of a large number of grain boundaries in nanostructured ceramics completely changes the field distribution inside the ceramic volume into a highly inhomogeneous one, as demonstrated by FEM calculations (Curecheriu *et al.*, 2010; Padurariu *et al.*, 2012; Padurariu and Mitoseriu, 2016b; Wu *et al.*, 2016). Due to the electrical boundary conditions, the highest voltage is practically applied onto the low-permittivity grain boundaries which are placed perpendicular to the field lines (Fig. 12) (Padurariu *et al.*, 2012).

Due to this effect, the permittivity is diminished and the breakdown field is much higher in nanostructured ferroelectric ceramics than in the coarse ones, as it was experimentally noticed and demonstrated by estimating the breakdown probability by phase field and FEM calculations (Fig. 13) (Cai *et al.*, 2018). Under the same applied field, the finer ceramics show a lower discharge energy density, but higher storage efficiency. Therefore, ultrafine ceramics meet the necessary requirements for being used in applications for electrostatic energy storage devices.

Grain size effects

In order to predict the role of reducing grain size on the phase transformation, polarization, tunability, switching character or piezoelectric properties as a function of grain size and of the electrical properties of core and shell components, the local field calculations by FEM approach in such core-shell (ferroelectric – linear dielectric) structures were usually completed with Landau-Devonshire – based theories (Fang *et al.*, 2010), nucleation-growth models (Boddu *et al.*, 2017) or Preisach approach (Padurariu and Mitoseriu, 2016b; Skaliukh, 2018) for switching. For example, by using a Landau-based model for the permittivity versus field dependence (Johnson approach) for the ferroelectric component, the dependence of permittivity versus applied electric field at various grain sizes for BaTiO₃ ceramics with sizes down to 100 nm was predicted, in an excellent agreement with experimental data (Fig. 14) (Padurariu *et al.*, 2012).

The electric field concentration in some specific regions such as grain boundaries, in the vicinity of pores or structural defects, gives rise to a higher probability for electrical failure (electrical breakdown) and this is detrimental in particular for high voltage applications of electroceramics, as for example for electrostatic energy storage capacity. Besides reducing ceramic grain size, in order to increase the breakdown field, it is necessary either to eliminate defects or to reduce the field concentration near defects. For these reasons, grain boundary-engineered composites formed by ferroelectric ceramic-glass core-shell structures were proposed (Wu *et al.*, 2016). In such structures, as for example in BaSrTiO₃@SiO₂, the absence of interfacial defects allows the design of higher energy storage capacity ceramics by grain boundary engineering (Wei *et al.*, 2013; Elissalde *et al.*, 2015; Wu *et al.*, 2016; Huang *et al.*, 2018).

Description of Domain Structure and Switching Properties of Ferroelectric Ceramics

The paraelectric-to-ferroelectric transition in oxide ferroelectrics is accompanied by lattice strains which cause local deformations and internal mechanical stresses, depending on the boundary constraints. The formation of regions with oriented domains (ferroelectric domain structure) separated by discontinuity regions (domain walls) takes place in order to minimize the system’s free energy, i.e., the electrostatic and internal mechanical stress contributions. The spatial distribution of domains and domain

walls, their structure, patterns, mobility and defects associated to their formation strongly affect the macroscopic dielectric, piezo-, pyro- and ferroelectric properties of materials (Rödel, 2007; Weng and Wong, 2009). The artificial domain patterning is of high interest due to the possibility of exploiting engineered domain configurations to enhance properties necessary in applications like memories, sensing and actuation or energy harvesting (Weng and Wong, 2009; Muench *et al.*, 2019). Field-induced ferroelectric switching is the irreversible (hysteretic) distinctive phenomenon characteristic of ferroelectric materials, involving the nucleation of new domains and domain wall motion under applied electric fields. The ability to predict domain evolution under applied fields and/or stresses is crucial for fundamental understanding of polarization switching mechanisms in ferroelectric ceramics and for technological applications and it was mostly analyzed for single crystalline structures (Potnis *et al.*, 2010; Boddu *et al.*, 2017).

Modeling domain structure in polycrystalline ceramics with realistic microstructure is not a simple task, because it involves the description of complex movements of both ferroelectric and ferroelastic (180° , 90° , etc.) domain walls under specific electrical and mechanical boundary conditions. The three main theoretical approaches used to model the ferroelectric switching and domain structures in BaTiO_3 -like materials are: phenomenological, first-principles and force field-based methods.

The phenomenological methods (Landau-based approaches) describe the free energy of the system as a polynomial expansion of polarization, strain, temperature and external electric field without considering the atomic structure of the system. A further development are the phase-field models, additionally considering the local inhomogeneities with domain-domain interactions and long-range order electric and elastic fields (Choudhury *et al.*, 2005; Chen, 2008; Koyama and Onodera, 2009).

The first-principles methods, such as the density functional theory (DFT) have been applied for small lengths (~ 5 nm) and short time scales (~ 100 ps) only because of high computational costs, restricting investigations of hysteresis loops, sequential phase transitions and domain wall motion occurring at larger length scale (~ 10 – 100 nm) and timescale (larger than ns) (Cohen and Krakauer, 1990; Piskunov *et al.*, 2004).

Force field – based approaches (e.g., shell model, effective Hamiltonian model and bond valence) provided a higher computational speed to perform molecular dynamics (MD) simulations and allowed to compute properties of larger system and at larger time-scales, thus enabling to derive the full chemistry of ferroelectric perovskites, to evaluate the influence of surface chemistry and of oxygen defects on the ferroelectric response, to describe the succession of structural transitions, ferroelectric and thermal hysteresis loops, domain wall movement and polarization responses (Piskunov *et al.*, 2004; Akbarian *et al.*, 2019).

In polycrystalline ceramics, there are two microstructural levels to be described: grain structure (simulated by grain growth models as described in paragraph Section Models for Describing the Sintering Process and Microstructure Evolution in Electroceramics) and domain structure of each individual grain (Choudhury *et al.*, 2007), which were usually described by the inhomogeneous distribution of local polarization components of the polarization vector in the local coordinate system (Choudhury *et al.*, 2007). The total free energy of a ferroelectric polycrystalline ceramic contains the bulk free energy described as a Landau series expansion vs. local polarization terms, an elastic energy component due to the coupling between the strain-stress field (electrostriction terms), an electrostatic energy term (containing the contribution from the external applied field, dipole-dipole interaction and depolarization energy) and a gradient energy which is non-zero only around domain walls and grain boundaries (Choudhury *et al.*, 2007; Su *et al.*, 2015; Li and Wang, 2017). In such calculations, the equilibrium state is obtained when the minimum value of the free energy was reached. By using this approach, the role of grain size on the as-born domain structure (PbTiO_3 ceramic in the virgin state) (Fig. 15) or after the polycrystalline system was subjected to various field sequences (Choudhury *et al.*, 2007) or poling/depolarization processes was determined. The role of non-ferroelectric grain boundaries in

Effect of grain orientation and grain size on ferroelectric domain switching and evolution: Phase field simulations. *Acta Materialia* 55 (4), 1415–1426. doi:10.1016/j.actamat.2006.09.048, with permission.

Fig. 16 Simulated grain size dependence of butterfly loops of BaTiO₃ at two frequencies by considering “dead-layer” model for grain boundaries: (a) 25 Hz, (b) 100 Hz; distribution of polarization vectors at zero field for two grain sizes: (c) 100 nm, (d) 20 nm size. Adapted from Su, Y., Liu, N., Weng, G.J., 2015. A phase field study of frequency dependence and grain-size effects in nanocrystalline ferroelectric polycrystals. *Acta Materialia* 87, 293–308. doi:10.1016/j.actamat.2015.01.015, with permission.

core-shell polycrystalline structures or in nanostructured ceramics with various grain sizes on the domain formation and on the $P(E)$ hysteresis responses were also simulated (Su *et al.*, 2015; Li and Wang, 2017).

For example, the results of such calculations show that when reducing the grain size of polycrystalline ceramics, a decrease of the polarization values and of $P(E)$ and $\varepsilon(E)$ loops area is noticed, together with modifications of local domain structures, as result of inactive non-ferroelectric grain boundaries (“dead layers”) (Figs. 16 and 17) (Su *et al.*, 2015; Li and Wang, 2017). These trends have been experimentally observed, as well.

Additionally, the polarization, strain, permittivity vs. field or stress responses under various conditions (temperature, electrical and mechanical inputs, their history or frequency) or the role of charged or dipolar defects acting as pinning centers were also simulated by using various approaches (Shu *et al.*, 2012; Su *et al.*, 2015; Li and Wang, 2017; Yang *et al.*, 2018; Zhao and Soh, 2020). In this way, both local features (e.g., the modification of domain structure at grain boundaries or around pinning centers or defects, topological structures as vortex dipolar domain structures), free energy modifications in the range of phase superposition or morphotropic phase boundaries, as well as the corresponding macroscopic average electrical or electromechanical responses (e.g., defects-induced shifts of the polarization or strain versus field loops) (Yang *et al.*, 2018) have been simulated and compared with experimental features (Fig. 18).

The most complex approach in describing polycrystalline ceramics is the hierarchical multiscale modeling which would allow the best resolution in a broad length- and time-scale, and involves a set of integrated computational methods enabling to bridge from nano to macroscale properties (Tan and Kochmann, 2017). The constitutive model with increasing complexity starts from the description of single-domain ferroelectric, then it extends to single crystals with a multiple domain structure and ends with the description of an effective polycrystalline ceramic material with its complex domain structure, as schematically represented in Fig. 19 (Tan and Kochmann, 2017).

Results from atomistic, molecular, or mesoscale simulation may feed into constitutive equations or continuum models for describing mesoscale properties (domain structures, grain boundary phenomena) and their statistical averaging will provide

information about the macroscopic responses (Tan and Kochmann, 2017). The multiscale simulations could play an important role in material science and technology by providing predictive functional material properties as a result of micro- and meso-scale engineering.

Conclusions

A few examples of theoretical and modeling approaches regarding the description of ferroelectric polycrystalline ceramics, in particular ferroelectrics, have been presented. The complexity of such non-linear materials in which electrical, mechanical and thermal constraints are coupled cannot be exhaustively described by a simple modeling approach. The development of optimized approaches and computing inexpensive tools able to provide material responses describing the observed experimental properties is of high interest. Screening new or tailored electroceramic materials (in terms of chemical or crystalline phase composition, connectivity degree in composites, porosity or grain size) for exploring new or enhanced functionalities is an essential task in wide range technological areas. Optimized computational methods and simulation efforts are therefore highly necessary in order to reduce the time and costs associated to material synthesis and characterization.

Introduction

Barium titanate, BaTiO₃, has been the first ferroelectric and piezoelectric ceramic developed for commercial applications and it is still widely used, especially as a high permittivity dielectric in multilayer ceramic capacitors (MLCCs) and as a semiconducting material in thermistors with positive temperature coefficient of resistivity (PTCR). A detailed chronology of the discovery and important scientific contributions on the understanding and use of BaTiO₃ was written by [Randall *et al.* \(2004\)](#). According to [Jaffe *et al.* \(1971\)](#) and [Haertling \(1999\)](#), there were three basic steps in the discovery and understanding of ferroelectricity and piezoelectricity in BaTiO₃ which have later paved the way to the development of the entirely new class of ferroelectric ceramic materials with perovskite structure.

The first one, the observation of an unusually high dielectric constant in barium titanate, was independently done in USA, former URSS and Japan during World War II ([Randall *et al.*, 2004](#)). The second step was the realization that the cause of the high permittivity was ferroelectricity ([Wul and Goldman, 1945](#); [von Hippel *et al.*, 1946](#)). Prior to 1940 only two ferroelectric crystals were known, Rochelle salt (potassium sodium tartrate) and potassium dihydrogen phosphate. However, BaTiO₃ has better properties, higher chemical stability and wider temperature range of operation. The third and very important step was the discovery of the “poling” process ([Grey, 1949](#); [Roberts, 1947](#)). The application of a strong electric field orients the polarization of the ferroelectric domains within the grains along the direction of the external field and this “poled” state remains even after the removal of the field. Thus, even the ceramic, despite its polycrystalline nature, behaves like a single crystal showing useful pyroelectric and piezoelectric properties. In fact, unpoled ceramics are not piezoelectrically active because the contribution of the randomly oriented grains would, on the whole, cancel out each other. This breakthrough was of fundamental importance for the large scale production and application of ferroelectric materials, as ceramics are much cheaper than single crystals and their properties, though inferior to those of single crystal, can be more easily tailored.

The crystal structure of BaTiO₃ and the origin of ferroelectricity in this compound from the cooperative ordering of the electrical dipoles arising from the deformation of the prototype perovskite cubic cell was established by [Rooksby \(1945\)](#), [Megaw \(1945\)](#), and [Kay and Vousden \(1949\)](#). The phenomenological theory of phase transitions and properties of barium titanate was introduced by [Devonshire \(1949\)](#). This thermodynamic theory was later used for describing ferroelectricity in many perovskite-type crystals and related structures. The temperature dependence of polarization, permittivity and optical properties in BaTiO₃ single crystals was determined by [Mertz \(1949\)](#), who related the observed variations to the deformations of the lattice. Later, the same author investigated the pressure and electric field dependence of the Curie temperature and interpreted the results using Devonshire's theory ([Mertz, 1950, 1953](#)). The domain structure and the domain switching, which largely affect all properties related to ferroelectricity, were studied, among the others, by [Matthias and von Hippel \(1948\)](#) and by [Merz \(1954\)](#).

The PTCR effect consists of an anomalous steep increase of resistivity of BaTiO₃ (up to 5–6 orders of magnitude) at the tetragonal to cubic phase transition temperature ([Jonker, 1964](#); [Heywang, 1971](#)) and has led to several applications as self-regulating heaters and over-current protection systems. This phenomenon is only observed in polycrystalline BaTiO₃, with the spontaneous polarization of the ferroelectric domains modifying the band-bending and, therefore, the electronic transport across the grain boundary.

In spite of more than 70 years of continuous investigation, barium titanate still attracts great attention as a model ferroelectric system and key components of materials for applications in capacitors, lead-free piezoelectric devices, ceramics and composites for energy storage ([Acosta *et al.*, 2017](#); [Yao *et al.*, 2017](#); [Palneedi *et al.*, 2018](#); [Prateek *et al.*, 2016](#)). According to Web of Science, about 15,000 papers containing “BaTiO₃” or “barium titanate” in their title have been published since 1965. The reasons behind this success are manifold: (1) simple composition and structure; (2) high stability and ease to adapt the properties to the specific application by doping, formation of solid solutions with other perovskites and tailoring of microstructure; (3) relatively simple and cheap processing especially in the case of ceramics; (4) lack of effective competitors in core applications.

Crystal Structure, Nonstoichiometry and Defect Chemistry of BaTiO₃

The BaO–TiO₂ phase diagram shown in [Fig. 1\(a\)](#) ([Lee *et al.*, 2007b](#)) presents at least 9 ternary compounds which have been proven to be useful as electroceramics, with the most important being the perovskite BaTiO₃ for its application in MLCCs and PTCR devices. [Rase and Roy \(1955\)](#) published in 1955 a phase diagram in which many phase relationships were clarified. This phase diagram was further modified by [O'Bryan and Thomson \(1974\)](#), [Negas *et al.* \(1974\)](#), [Ritter *et al.* \(1986\)](#) and, most recently, by [Lee *et al.* \(2007b\)](#).

Below 1460°C, BaTiO₃ possesses the perovskite structure. At higher temperature a hexagonal polymorph (6H-type, s.g. *P63/mmc*) with non-perovskite structure appears. The perovskite to 6H transition temperature is very sensitive to the presence of acceptor dopants, as discussed in Section “Incorporation of Transition Metal Ions and Other Acceptors”.

The perovskite form of BaTiO₃ exhibits different crystallographic variants, depending on temperature (Megaw, 1945; Kay and Vousden, 1949; Kwei *et al.*, 1993), as shown in Fig. 2. The high-temperature cubic form has the prototype ABO₃ (with Ba²⁺ as A and Ti⁴⁺ as B) perovskite structure. This is a centrosymmetric structure with Ba²⁺ at the corners, Ti⁴⁺ at the center, and the oxygen at the face centers. The titanium ion is octahedrally coordinated by six oxygen ions while Ba²⁺ has a dodecahedral coordination. At the Curie temperature, $T_C = 120\text{--}130^\circ\text{C}$, it turns from the high temperature paraelectric cubic form (*C*, *Pm* $\bar{3}$ *m*) to the ferroelectric tetragonal structure (*T*, *P4mm*). On further cooling, two other ferroelectric phases are observed: orthorhombic (*O*, *Amm*2), below $5\text{--}15^\circ\text{C}$, and rhombohedral (*R*, *R*3*m*), below -80 to $(-90)^\circ\text{C}$. Discontinuities of the small signal dielectric constant are observed at the transition temperatures (Fig. 2). All polar forms originate from a small deformation of the prototype cubic lattice arising from the off-center displacement of the Ti ion (about $0.1\text{ \AA}$ at room temperature) in the TiO₆ octahedron. Each of these variants can be thought as deformations of the cubic unit cell along an edge ([001], tetragonal), along a face diagonal ([011], orthorhombic), or along a body diagonal ([111], rhombohedral). Likewise, the orientation of the electrical dipole is [001], [011] and [111] for the *T*, *O* and *R* modifications, respectively. The cooperative, long-range ordering of the electrical dipoles gives rise to macroscopic spontaneous polarization (P_s), spontaneous lattice strain and ferroelectricity (Damjanovic, 1998). At room temperature the ratio c/a of the lattice parameters of the tetragonal cell ($a = b$, $c > a$) is 1.011, i.e., the deformation and, consequently, the spontaneous strain is of the order of 1%. At -93°C the rhombohedral angle α is 89.85° (Kwei *et al.*, 1993), i.e., there is only a deviation of 0.15° from the cubic lattice. Despite the small deformation, P_s takes significant values, up to $20\text{--}25\text{ }\mu\text{C}/\text{cm}^2$ at room temperature. The spontaneous polarization can be switched between energetically equivalent orientations

Fig. 2 (a) Temperature dependence of crystal structure and relative dielectric constant along the a-axis direction in BaTiO₃ single crystal. The Ti off center displacement is exaggerated to be better observable. Dielectric constant data from ref. Mertz, W.J., 1949. The electric and optical behavior of BaTiO₃ single-domain crystals. *Physical Review* 76, 1221–1225.

Fig. 3 Polarization (P) – electric field (E) ferroelectric polarization loop.

(6, 12 and 8 for the T, O and R phase, respectively) by means of an electric field. Polarization switching is a hysteretic process; by plotting the polarization P against the amplitude of the ac electric field E , the ferroelectric hysteresis loop is obtained (**Fig. 3**). The polarization at zero field is called remanent polarization (P_r) and the field at zero polarization is the coercive field (E_c). The switching process requires the application of a field larger than E_c . Polarization and strain are strongly coupled in ferroelectrics: a modification of the strain state determines a variation of polarization and vice versa. Because of the strong coupling between polarization and lattice strain and the often incomplete surface charge screening, the properties of ferroelectric materials are also very sensitive to the mechanical and electrical boundary conditions ([Damjanovic, 1998](#)).

Ferroelectric crystals spontaneously split into domains when cooled through the Curie temperature. Domains are regions with uniform orientation of polarization separated by domain walls. In tetragonal BaTiO₃, there are two kinds of domain walls, which separate regions with mutually antiparallel (180° walls) or perpendicular (90° walls) orientation of polarization. The other ferroelectric phases of barium titanate have a higher number of domain variants, corresponding to 3 and 4 different kinds of domain walls for the R and O phase, respectively. Domain formation occurs to minimize the elastic and electrostatic energies. In a ceramic, elastic energy in individual grains originates from the variation of lattice parameters and unit cell volume as the material crosses the paraelectric/ferroelectric transition on cooling, owing to the mechanical constraints exerted by the surrounding grains. Formation of 90° domain walls relieves the elastic energy. The electrostatic energy is associated with the depolarizing field produced by the surface charges at the termination of the material. Formation of both 90° and 180° walls relieves the electrostatic

energy. Domain walls can move under the action of an external electric field or a mechanical stress. The movement of domain walls at weak to moderate fields is one of the most important so-called extrinsic (non-lattice) contributions to the dielectric, elastic and piezoelectric properties of ferroelectric materials and may be comparable to the intrinsic effect of the lattice (Acosta *et al.*, 2017; Damjanovic, 1998). The movement of the domain walls is also responsible for the reorientation and switching of the polarization and the existence of the ferroelectric hysteresis loop.

Although for the purpose of this chapter we consider the phase transitions in BaTiO₃ as purely displacive, their actual nature has been debated. There is some evidence provided by extended X-ray absorption fine structure (EXAFS), nuclear magnetic resonance (NMR) and the pair-distribution function (PDF) investigations that the local structure of BaTiO₃ is different from the average one presented above and remains rhombohedral at all temperatures (Comes *et al.*, 1968; Kwei *et al.*, 1995; Ravel *et al.*, 1998; Zalar *et al.*, 2003; Levin *et al.*, 2014; Senn *et al.*, 2016). The results demonstrate the coexistence of displacive and order-disorder components in the phase transition mechanism. According to the eight-site model (Pirc and Blinc, 2004), the Ti ions in the paraelectric cubic phase exhibit off-center local displacement along the eight [111] directions but the average polarization is null because of the random distribution among the 8 split sites. Below the Curie temperature partial ordering occurs. Thus O, T and C long-range structures are the result of the averaging [111] displacements of octahedral Ti over 2, 4 and 8 local rhombohedral directions, respectively. Only for the rhombohedral phase the local and long-range structures are equivalent.

Lee and Randall (Lee *et al.*, 2008; Lee and Randall, 2008; Lee *et al.*, 2007a) spent a great deal of work in determining the homogeneity range of BaTiO₃ as a function of temperature and oxygen partial pressure and estimated the entropy and enthalpy of most important defect reactions. As already reported by Rase and Roy (1955), BaTiO₃ shows a non-negligible nonstoichiometry in the range 1000–1400°C. Non-stoichiometry is mainly associated to partial Schottky disorder:

where V_{Ba}'' and V_{Ti}''' denote a barium vacancy and a titanium vacancy, respectively, and $V_{\text{O}}^{\bullet\bullet}$ indicates an oxygen vacancy. Density functional theory calculations have shown that different combinations of barium vacancies, titanium vacancies and V_{Ti}''' - $V_{\text{O}}^{\bullet\bullet}$ pairs can be present in BaTiO₃ depending on processing and doping (Baker *et al.*, 2018). The homogeneity range attains the maximum width at 1320°C, the eutectic temperature of the BaO-TiO₂ system in air, with a Ba/Ti atomic ratio ranging from 0.967 to 1.01 (Lee *et al.*, 2007b, 2008). In other words, the solubility of TiO₂ in BaTiO₃ is larger than that of BaO. The nonstoichiometry within the homogeneity range of BaTiO₃ impacts on all intrinsic properties, including the Curie temperature, which can change up to 5–6°C moving throughout the solubility window, the enthalpy of transition (Lee *et al.*, 2007b, 2008; Lee and Randall, 2008; Lee *et al.*, 2007a) and the dielectric permittivity (Lee *et al.*, 2001).

At high temperature and low oxygen partial pressure, oxygen vacancies are also created by oxygen loss from the lattice of BaTiO₃ according to reaction:

where e' is an electron in the conduction band. The formation of electrons is associated to the reduction of Ti^{4+} ($3d^0$) to Ti^{3+} ($3d^1$) and the contribution of 3d orbitals to the conduction band. If n is the concentration of conducting electrons, the charge neutrality condition implies $n = 2[V_{\text{O}}^{\bullet\bullet}]$. The homogeneity range of BaTiO₃ decreases with decreasing the oxygen pressure (Lee and Randall, 2008) as the formation of oxygen vacancies in reaction (2.3) shifts reactions (2.1) and (2.2) to the left (Fig. 1(b)).

The defect chemistry of undoped barium titanate as a function of oxygen partial pressure was carefully investigated using high-temperature electrical conductivity measurements (Long and Blumenthal, 1971a,b; Chan *et al.*, 1981; Smyth, 1985) and the results could be explained by a relatively simple model. The equilibrium conductivity (Fig. 4) shows regions corresponding to the reduction regime (n -type conductivity) and the oxidation regime (p -type conductivity) below and above a conductivity minimum located at an oxygen partial pressure $p_{\text{O}_2} = p_{\text{O}_2}^0$, whose value depends on temperature. In the reduction regime the conductivity increases with decreasing p_{O_2} according to reaction (2.3). However, this reaction becomes the major source of defects only at low oxygen partial pressure, where the slope of the conductivity curve in Fig. 4 is $-1/6$. Over most of the experimental range shown in Fig. 4, the accidental acceptor impurities and their compensating oxygen vacancies are the dominant defects, and the condition of charge neutrality can be approximated by $[A'] = 2[V_{\text{O}}^{\bullet\bullet}]$, where $[A']$ represents the net concentration of acceptor impurities (see Section "Incorporation of Foreign Ions" for a more detailed discussion). Acceptor impurities, such as Al and Fe incorporated at the Ti site as well as Na and K incorporated at the Ba site usually predominates over donor impurities. If Ba/Ti $\neq$ 1 and the concentration of acceptor impurities is low, the dominating defects will be cation vacancies and oxygen vacancies (reaction (2.1) or (2.2)). Under both the above conditions, the slope of the conductivity curves in Fig. 4 is $-1/4$. In the oxidation regime above $p_{\text{O}_2}^0$, oxygen is incorporated in the perovskite lattice by reaction:

where $h^{\bullet}$ is an electron hole in the valence band. This determines an increase of the conductivity with increasing oxygen partial pressure with $+1/4$ slope in Fig. 4. Oxygen vacancies exist also in the oxidation regime owing to the presence of a net excess of acceptor impurities or nonstoichiometry.

Fig. 4 Equilibrium electrical conductivity of polycrystalline BaTiO₃ at 600–1000 °C with 50 °C interval. Data from ref. Smyth, D.M., 1985. Defects and order in perovskite-related compounds. Annual Review of Material Science 15, 329–357.

Strategies for Modifying Defect Chemistry, Phase Transitions and Properties

Undoped barium titanate ceramics and single crystals have limited interest for applications as their dielectric, electromechanical and optical properties show a significant temperature dependence (see the variation of dielectric constant in Fig. 2 as an example) whereas, in most cases, a better thermal stability is needed. On the other hand, the strong increase of the dielectric and piezoelectric properties approaching the phase transition temperatures (Mertz, 1953; Acosta *et al.*, 2017) would be of high interest for the fabrication of devices with better performances. The development of BaTiO₃-based materials and their use in commercial applications has been driven by the need to find a compromise between these two contrasting trends.

Chemical modification represents the most common and simple approach for tuning the phase transitions and the properties of barium titanate and other ferroelectric perovskites such as Pb(Zr,Ti)O₃, (K,Na)NbO₃ and Na_{0.5}Bi_{0.5}TiO₃. The term doping is usually used to indicate the substitution of a limited amount of parent ions, typically less than a few at%. Even a very small amount of dopant can considerably modify functional properties like the electrical conductivity and the domain wall mobility. When a substantial amount of foreign ions is incorporated in the lattice is more appropriate to refer to formation of solid solutions. Chemical modification is essential to shift the phase transition temperatures and in particular to lower T_C around room temperature and modify the nature of the phase transition. The formation of solid solutions introduces disorder and local compositional fluctuations with a decrease of the dipole correlation length, coexistence of polymorphs and diffuse phase transitions over a relatively large temperature range leading to broad permittivity peaks. Doping is also essential to impart the material a number of characteristics essential for its processing and reliability under operating conditions. Typical examples include resistance to degradation of dielectric properties during sintering in reducing atmosphere (essential for the fabrication of capacitors with non-noble metal electrodes), high insulation resistance, resistance to ageing and cycling, control of domain wall mobility. In general, the final properties are the result of a complex interplay between alteration of defect chemistry, shift and modification of phase transitions, changes in crystal structure (average and local) and polar order.

Dielectric and piezoelectric properties can also be controlled by modifying the microstructure and, in particular, by optimizing the grain size. It is well known that the permittivity and the piezoelectric activity of BaTiO₃ ceramics are maximized for a grain size of $\approx 1 \mu\text{m}$. A further strategy commonly used to improve the dielectric properties for capacitor application is the fabrication of ceramics with core-shell grains, which combines the chemical modification with the control of microstructure and formation of compositional gradients.

Incorporation of Foreign Ions

Substitution of a regular ion (Ba^{2+} or Ti^{4+}) with a foreign ion determines the formation of a point defect (Smyth, 1985). If the substituent cation has a higher positive charge than the ion it replaces (e.g., M^{3+} at the Ba site), it is termed a “donor” and will assume an effective positive charge in the oxide lattice ($M_{\text{Ba}}^{\bullet}$). This positive charge will be compensated by defects with a negative charge, most commonly cation vacancies ($V_{\text{Ti}}^{\prime\prime\prime}$, $V_{\text{Ba}}^{\prime\prime}$) or electrons (e') in the conduction band.

Fig. 5 Schematic representation of the room-temperature dc resistivity as a function of the trivalent dopant concentration M^{3+} for ceramics sintered in air. Adapted from ref. Morrison, F.D., Sinclair, D.C., West, A.R., 2001b. Alternative explanation for the origin of the resistivity anomaly in La-doped BaTiO₃. *Journal of the American Ceramic Society* 84, 474–476.

The formation of electrons is associated to the reduction of Ti^{4+} ($3d^0$) to Ti^{3+} ($3d^1$) and the contribution of 3d orbitals to the conduction band. A reaction similar to (3.1) can be written for barium vacancy compensation. According to available literature, titanium vacancies are preferred over barium vacancies as charge compensating defects especially if the dopant concentration is high (Jonker and Havinga, 1982; Chan *et al.*, 1986; Shaikh and Vest, 1986; Morrison *et al.*, 2001a). Most common donors are pentavalent ions such as Nb^{5+} , Ta^{5+} and Sb^{5+} substituting at the Ti site and large trivalent lanthanide ions (La^{3+} , Nd^{3+} , Ce^{3+} , etc.) substituting at the Ba site.

If the foreign cation has a lower charge than the regular ion it substitutes, it is called an “acceptor” and will assume an effective negative charge compensated by positively charged defects, either oxygen vacancies ($V_O^{\bullet\bullet}$) or electron holes ($h^\bullet$) in the valence band.

Common acceptors are monovalent ions (Ag^+ , Na^+ , K^+ , etc.) incorporated at the Ba site and all ions with charge lower than 4 (Li^+ , Mg^{2+} , Ca^{2+} , Ni^{2+} , Sc^{3+} , Fe^{3+} , Lu^{3+} , Yb^{3+}) and compatible ionic radius incorporated at the Ti site.

For trivalent cations with an ionic radius intermediate between Ba^{2+} and Ti^{4+} , a further incorporation mechanism, termed “self-compensation”, corresponding to the simultaneous substitution at both cation sites, exists:

Finally, when the substituent cation and the regular cation have the same charge, a neutral defect will originate.

The electrostatic interaction between defects of opposite charge can lead to the formation of defect pairs and defect clusters. These clusters, especially those formed by transition metal acceptors (Fe^{3+} , Mn^{3+} , Mn^{2+}) with a neighboring oxygen vacancy, interact with the domain walls and have a strong effect on the ferroelectric and piezoelectric properties (Jin *et al.*, 2014).

The prevailing charge compensation mechanism (cation vacancies or electrons, oxygen vacancies or holes) is determined by the formation energy of the defects, the oxygen partial pressure and the dopant concentration. For donor doping, electron compensation will prevail in reducing conditions (the Ti^{4+} ions will be progressively reduced to Ti^{3+} with decreasing oxygen activity) while titanium vacancies will dominate in oxidizing atmospheres (Makovec and Drofenik, 2000). When reaction (3.2) prevails, a plateau on the conductivity vs. oxygen pressure is observed as the number of charge carriers is determined by the donor concentration (Daniels and Härdtl, 1976; Chan and Smyth, 1984). Donor-doped BaTiO₃ ceramics sintered in air can be either semiconducting or insulating at room temperature depending on the doping level and ceramic processing conditions (Fig. 5). With increasing donor concentration, the resistivity decreases from $\approx 10^{10} \Omega \cdot cm$ of neat BaTiO₃ (point 1 in Fig. 5) down to a minimum of 10^2 – $10^1 \Omega \cdot cm$ (point 2 in Fig. 5) for a doping level of, typically, 0.2–0.3 at% (Jonker, 1964; Morrison *et al.*, 2001a). For higher doping levels the resistivity rises and the material becomes again insulating (point 3 in Fig. 5). This behavior is usually interpreted as a crossover in the charge compensation mechanism, from prevailing electron compensation to cation vacancy compensation. However, this interpretation is still controversial. Morrison *et al.* (2001a,b), on the basis of a detailed study of La-doped samples, concluded that charge compensation always occurs by cation vacancies and that semiconductivity in BaTiO₃ is determined by oxygen nonstoichiometry and reduction of Ti^{4+} to Ti^{3+} , as described by reaction (2.3). However, this conclusion was criticized by Smyth (2002), based on (1) the existence of a p_{O_2} -independent conductivity plateau proportional to the donor

concentration in donor-doped samples and (2) a reversible weight change determined by the release of excess oxygen contained in La₂O₃ (reaction (3.2)) again proportional to the donor concentration. More recent atomistic simulations have shown that oxygen loss by reaction (2.3) is much more favorable in La-doped BaTiO₃ than in the undoped material when compensation occurs by cation vacancy due to the formation of unique defect clusters involving the different point defects (Freeman *et al.*, 2013).

In the interpretation of the resistivity anomaly (Fig. 5) it should also be considered that the ceramics are not in equilibrium at room temperature and that the defect structure corresponds to that existing at an intermediate temperature between sintering temperature and room temperature. During cooling, reoxidation occurs according to the reverse of reactions (3.2) and/or (2.3) but the level and distribution of oxygen uptake on cooling and, consequently, the electrical properties depend on the sintering atmosphere, the cooling rate and the ceramic microstructure. Lowest values of resistivity are observed for coarse grained ceramics rapidly cooled. In contrast, fine grained ceramics slowly cooled tend to exhibit higher values of resistivity. However, coarse ceramics are highly heterogeneous from the point of view of resistivity, with semiconducting grains and more insulating, reoxidized grain boundaries. This heterogeneous electrical structure is at the root of the PTCR effect (Heywang, 1971). The partial reoxidation of grain boundaries determines the development/enhancement of the Schottky barriers which is required for the appearance of this non-ohmic effect. Depending on processing conditions, a fully reoxidized and insulating skin can appear on the ceramic surface (Morrison *et al.*, 2001c).

Materials with stoichiometry corresponding to reaction (3.2) sintered at low oxygen partial pressure are single phase and conducting even for large values of the dopant fraction of the order of 10 at% (Makovec and Drofenik, 2000). In this case, the donors are effectively compensated by the formation of electrons/Ti³⁺ ions.

Incorporation of Transition Metal Ions and Other Acceptors

In many cases the transition metal ions exhibit +2 and +3 charge and, due to their relatively small ionic radius, they usually substitute Ti⁴⁺ and act as acceptors. Doping of BaTiO₃ with ions of 3d transition metals, especially Fe, Mn and Co, has been widely investigated as they are quite effective as modifiers of the ferroelectric properties leading to constrained and asymmetric P (E) loops (Jin *et al.*, 2014; Hall *et al.*, 1998). The oxygen vacancies created as charge compensating defects can form defect dipoles with the acceptor ions (e.g., $Fe_{Ti}' - V_O^{\bullet\bullet}$) which stabilize the domain walls and clamp their motion ("hardening" effect) (Zhang *et al.*, 2008; Erhart *et al.*, 2007). Poled acceptor-doped BaTiO₃ ceramics can be used as highly linear piezoelectric transducers and actuators with low hysteresis and dissipation for high power/frequency applications (Zhang *et al.*, 2009). Transition metal ions and other acceptors are also quite effective (reaction (3.3)) to suppress oxygen loss and conductivity increase related to reaction (2.3) when sintering BaTiO₃ in reducing atmosphere, leading to insulating ceramics suitable for the preparation of MLCCs with non-noble metal (e.g., Ni) internal electrodes (Hagemann and Hennings, 1981).

More recently, BaTiO₃ ceramics doped with magnetic transition metal ions have attracted interest as potential multiferroic and magnetoelectric materials because of the appearance of weak magnetism (Raj *et al.*, 2008; Xu *et al.*, 2009; Lin *et al.*, 2009; Son *et al.*, 2013). However, when the dopant amount exceeds few at%, formation of the non-ferroelectric hexagonal polymorph (6H-type, s.g. *P63/mmc*) instead of the perovskite phase is observed.

Stabilization of the hexagonal modification

The perovskite/hexagonal structural transition has been investigated in some detail. In undoped BaTiO₃ the 6H polymorph is stabilized by sintering or annealing in a reducing atmosphere or quenching from a temperature above 1430–1460°C (Glaister and Kay, 1960; Kolar *et al.*, 1998; Sinclair *et al.*, 1999). The incorporation of transition metal ions (BaTi_{1-x}B_xO_{3-δ}, B = Fe, Mn, Ni, Co, Cr, Cu) stabilizes the 6H-phase below the transition temperature of 1460°C reported of pure BaTiO₃ (Fig. 1). In the case of Fe, the transition temperature decreases rapidly and attains ≈ 1300°C for $x = 0.05$ and $1150 \pm 50^\circ\text{C}$ for $x = 0.10$ (Masó *et al.*, 2006), as shown in Fig. 6. However, a mixture of 6H and perovskite phase persist at even lower temperatures. For example, for $x = 0.05$ a single phase perovskite is only obtained at temperatures ≤ 1100°C. The relative amount of the two polymorphs is very sensitive to several operating conditions, including the cooling rate, the composition of the sintering atmosphere and the annealing at temperatures below that of sintering (Langhammer *et al.*, 2000). The perovskite to 6H transformation is commonly accompanied by microstructural modifications and, in particular, by the growth of large plate-like hexagonal grains (Kolar *et al.*, 1998; Langhammer *et al.*, 2000). Stabilization of 6H-phase has been attributed to different reasons, including: (1) the formation of oxygen vacancies, (2) the Jahn-Teller effect related to specific configurations of the *d*-electrons, and (3) metal-metal bonding of cations through the face sharing octahedra existing in the 6H-phase. Since the stabilization of the hexagonal polymorph has also been observed for acceptors without *d*-electrons (Mg²⁺, Al³⁺) or with filled *d*-orbitals (Zn²⁺, Ga³⁺, In³⁺) (Keith *et al.*, 2004), the most important factor is likely to be the oxygen vacancies. However, other effects can be of some importance and, for example, can play a role in the different solubility of the acceptors. Extensive solid-solutions were reported for Fe- and Mn-doped ceramics, while for many other acceptors the maximum solubility is of the order of 10 at% (Keith *et al.*, 2004; Das *et al.*, 2014). Two series of 6H-BaTi_{1-x-y}Fe_x³⁺Fe_y⁴⁺O_{3-x/2} solid solutions with iron predominantly in the form Fe³⁺ or Fe⁴⁺ were reported by quenching from high temperatures in air or slow cooling to 200°C in oxygen, respectively (Grey *et al.*, 1998). In the first case, Fe³⁺ behaves as an acceptor and oxygen vacancy formation occurs up to $x = 0.67$ (corresponding to $\delta = 0.33$ in BaFe_xTi_{1-x}O_{3-δ}). Higher values of x resulted in the conversion of 6H in other phases. Differently, the oxidation of iron to Fe⁴⁺ avoids the formation of charge compensating defects and complete solubility exists between BaTiO₃ ($x = 0$) and BaFeO₃ ($x = 1$). The existence of two different

Fig. 6 Phase diagram for the solid solution $\text{BaTi}_{1-x}\text{Fe}_x\text{O}_{3-\delta}$. T_C (IS) denotes Curie temperature obtained from impedance spectroscopy measurements. T_C (DSC) denotes Curie temperature obtained from differential scanning calorimetry. Reproduced from ref. Masó, N., Beltrán, H., Cordoncillo, E., Escribano, P., West, A.R., 2006. Electrical properties of Fe-doped BaTiO₃. *Journal of Materials Chemistry* 16, 1626–1633 by permission of The Royal Society of Chemistry. Copyright (2006) The Royal Society of Chemistry.

incorporation mechanisms is well evident from the opposite trend of the lattice parameters, as shown in Fig. 7. The deviation from the ideal behavior of $\text{BaTiO}_3\text{-BaFeO}_{2.5}$ and $\text{BaTiO}_3\text{-BaFeO}_3$ solid solutions indicates that iron is in a mixed valence state though one of the states predominates. The $\text{BaO-TiO}_2\text{-Fe}_2\text{O}_3$ phase diagram and the rich crystal chemistry in this system with 16 quaternary compounds were reviewed by Siegrist and Vanderah (2003). Manganese shows a behavior similar to iron as it can be incorporated at Ti site as Mn^{3+} with oxygen vacancy compensation or as Mn^{4+} or, again, in both forms depending on the annealing atmosphere and cooling rate (Miranda *et al.*, 2009).

Valence state of transition metal ions in the perovskite lattice

The oxidation number of the transition metal inside the BaTiO_3 lattice has been investigated also for low dopant concentrations (x up to 0.02) when the perovskite structure is stable. On the basis of magnetic susceptibility measurements on air-sintered ceramics, Ihrig (1978) determined that the +3 state prevails for iron, whereas manganese enters the lattice as Mn^{3+} and Mn^{4+} , and nickel is predominantly divalent. Incorporation of Cr^{4+} was suggested for chromium. The valence state of Cr, Mn and Co was found to change reversibly upon annealing at 700°C at different oxygen partial pressures (pure oxygen at 1.5×10^7 Pa, air and $\text{H}_2/\text{H}_2\text{O}$ mixture with $p(\text{O}_2) = 10^{-17}$ bar) whereas it remained constant for iron (Fe^{3+}) and nickel (Ni^{2+}) (Hagemann and Ihrig, 1979). While Cr^{4+} , Mn^{4+} and Co^{3+} prevail in pure oxygen, Cr^{3+} , Mn^{2+} and Co^{2+} predominate at low oxygen partial pressure. Similar conclusions on the valence states were attained by Hagemann and Hennings (1981) from the oxygen vacancy concentration data determined gravimetrically as a function of the oxygen partial pressure for samples containing 0.5 mol% dopant. The concentration of oxygen vacancies was fixed by the acceptor concentration (reaction (3.3)) down to $p(\text{O}_2) = 10^{-10}\text{--}10^{-12}$ Pa. At lower pressure the contribution of intrinsic vacancies from reaction (2.3) becomes increasingly important. Ozawa *et al.* (1993) measured the electrical conductivity of BaTiO_3 ceramics containing 2 at% Mn as a function of oxygen partial pressure ($10^{-10}\text{--}10^{-5}$ Pa) and concluded that at 900–1000°C, Mn^{3+} prevails at $p(\text{O}_2) < 1$ Pa, whereas Mn^{4+} predominates at higher pressure. The Electron Paramagnetic Resonance (EPR) measurements of Langhammer *et al.* (2015), (2008), Böttcher *et al.* (2011), Langhammer *et al.* (2003) generally confirmed the above trends. After sintering in air, cobalt is incorporated as a mixture of Co^{2+} and Co^{3+} , while Co^{2+} prevails after annealing in reducing atmosphere (Langhammer *et al.*, 2015). Likewise, the valence state of chromium changes from a value intermediate between +4 and +3 to +3 with decreasing oxygen partial pressure (Langhammer *et al.*, 2008). The EPR spectrum of Ni^{2+} was not detected in nickel-doped ceramics sintered in air in both the perovskite and hexagonal modifications (Böttcher *et al.*, 2011) and it was postulated that the dopant is mainly incorporated as Ni^{4+} in contrast with the results of Ihrig (1978). Copper is incorporated as Cu^{2+} after sintering in air (Langhammer *et al.*, 2003). Recent EPR results indicated that manganese behaves as an amphoteric dopant in SrTiO_3 lattice and can occupy both cation sites simultaneously as Mn^{2+} at the Sr site and $\text{Mn}^{3+}/\text{Mn}^{4+}$ at the Ti site (Maier *et al.*, 2016). This possibility should also be considered for BaTiO_3 .

Ni^{2+} and Fe^{3+} are quite effective to shift the Curie temperature down, about 30°C/at% for Ni^{2+} and 21°C/at% for Fe^{3+} , irrespective of oxygen partial pressure (Hagemann and Ihrig, 1979). Cr^{3+} and Co^{2+} are also good shifters (25 and 28°C/at%, respectively) but only in reducing atmosphere. Tetravalent chromium stabilizes the orthorhombic phase at lower temperature ($T_{\text{O/R}} = -80^\circ\text{C}$ for $x = 0$ and -105°C for $x = 0.02$) whereas most of the other ions shift the rhombohedral-orthorhombic transition to higher temperatures.

Formation of dipolar defects

The formation of nearest neighbors acceptor-oxygen vacancy pairs, ($M'_{Ti} - V_O^{\bullet\bullet}$) and ($M''_{Ti} - V_O^{\bullet\bullet}$), was also investigated by EPR in the case of Mn- and Fe-doped BaTiO₃ and PbTiO₃ (Zhang *et al.*, 2008; Erhart *et al.*, 2007). The dipolar defects align in the direction of spontaneous polarization by oxygen vacancy motion in the MO₆ octahedron and follow the domain switching upon poling (Erhart *et al.*, 2007; Warren *et al.*, 1996). The defect dipoles do not reorient during fast field cycling but reorientation rather requires long time, high thermal energy, and high electric fields. Ordering is destroyed above T_C and is not observed in SrTiO₃. The association enthalpy was determined as -0.26 eV (Merkle and Maier, 2003) for ($Fe'_{Ti} - V_O^{\bullet\bullet}$) in SrTiO₃, meaning that most of the dipolar pairs are dissociated above 300°C. Atomistic simulations performed on SrTiO₃ indicate association enthalpies in the range -0.25 to -0.5 eV for different transition metal acceptors (Schie *et al.*, 2014). Association enthalpies of -0.2 to (-0.3) eV are reported for defect pairs involving Mn''_{Ti} , Mn'_{Ti} and Fe'_{Ti} in BaTiO₃ (Merkle and Maier, 2003).

Incorporation of Rare-Earth Ions

Trivalent rare-earths cations (RE³⁺) of the lanthanide series show a progressively smaller ionic radius moving from La³⁺ ($r^{\text{XII}} = 1.36 \text{ \AA}$) to Lu³⁺ ($r^{\text{VI}} = 0.86 \text{ \AA}$), intermediate between Ba²⁺ ($r^{\text{XII}} = 1.61 \text{ \AA}$) and Ti⁴⁺ ($r^{\text{VI}} = 0.605 \text{ \AA}$). Although the +3 state is the most stable, some lanthanides also exhibit other oxidation states: +2 (Yb, Eu, Sm) and +4 (Pr, Ce, Tb). The specific valence exhibited by these ions depends on the sintering atmosphere and on the incorporation site. The mechanism of rare-earth cation substitution in BaTiO₃ has been investigated in detail (Xue *et al.*, 1988; Buscaglia *et al.*, 2000; Tsur *et al.*, 2001; Dunbar *et al.*, 2004) as it plays a key role in determining the properties and the reliability of MLCCs fabricated with the base metal electrode technology.

Incorporation site

For trivalent cations, the incorporation site is determined by the ionic radius. Large ions such as La³⁺ ($r^{\text{XII}}: 1.36 \text{ \AA}$), Ce³⁺ ($r^{\text{XII}}: 1.34 \text{ \AA}$) and Pr³⁺ ($r^{\text{XII}}: 1.29 \text{ \AA}$) exclusively substitute at the Ba site, acting as donors, while the smaller Lu³⁺ ($r^{\text{VI}}: 0.861 \text{ \AA}$) and Yb³⁺ ($r^{\text{VI}}: 0.868 \text{ \AA}$) prefer the Ti site, acting as acceptors (Xue *et al.*, 1988; Buscaglia *et al.*, 2000; Tsur *et al.*, 2001; Dunbar *et al.*, 2004; Makovec *et al.*, 1996; Lu *et al.*, 2014). Although it is reported that Nd³⁺ ($r^{\text{VI}}: 1.27 \text{ \AA}$) preferentially substitutes at the Ba site (Shaikh and Vest, 1986; Xue *et al.*, 1988; Buscaglia *et al.*, 2000; Tsur *et al.*, 2001; Dunbar *et al.*, 2004), Hirose *et al.* (1999) have shown that the mechanism changes from Ba-site substitution to self-compensation above $x = 0.05$ when Ba/Ti = 1. For all other cations, from Sm³⁺ to Tm³⁺, the substitution site can be controlled by adjusting the Ba/Ti ratio and, for this reason, they are often indicated as “amphoteric” dopants. Consequently, provided that the maximum solubility is not exceeded, the cation will occupy the Ba site when Ba/Ti < 1, the Ti site when Ba/Ti > 1 and both sites when Ba/Ti = 1. In the latter case, charge compensation defects are not needed (self-compensation, reaction (3.5)). The correct value of Ba/Ti required for the formation of the specific single phase solid solution can be determined taking into account the stoichiometry of the incorporation reactions (3.1)–(3.5). The solubility of the RE³⁺ ions at a given site is strongly dependent on ionic radius. For example, the solubility at Ba site with titanium vacancy compensation exceeds 20 at% in the case of La³⁺ (Morrison *et al.*, 1999) but drops to 5 at% for Gd³⁺ (Ben and Sinclair, 2011) and is only of the order of 1 at% for smaller lanthanides such as Y³⁺, Dy³⁺ and Er³⁺ (Zhi *et al.*, 1999; Lee *et al.*, 2000; Buscaglia *et al.*, 2002). Opposite, the solubility of small RE ions at the Ti site is much higher, of the order of 15 at% for Ho³⁺, Dy³⁺ and Y³⁺ (Zhi *et al.*, 1999; Lee *et al.*, 2000; Buscaglia *et al.*, 2002; Makovec *et al.*, 2004; Liu and West, 2009), and then rapidly decreases with increasing ionic radius (3.75 at% for Gd³⁺). However, the incorporation of a substantial amount of acceptor ions according to reaction (3.3) determines the formation of the hexagonal polymorph of BaTiO₃, likewise trivalent and divalent transition metal ions substituting at the Ti site. According to Liu and West (2009), 6H-BaTiO₃ forms as an intermediate kinetically stabilized phase before transforming into the thermodynamically stable perovskite phase after long-time annealing at high temperatures (> 1500°C). Prolonged annealing was also required to stabilize the perovskite phase in Er-doped ceramics (Buscaglia *et al.*, 2002). In contrast, the incorporation of Fe³⁺ and other transition metal ions shifts the polymorphic phase transition at lower temperatures and annealing is ineffective. Maximum solubility of amphoteric dopants is attained when the lanthanide occupies both sites and attains 24 at% in the case of Ho³⁺ (Makovec *et al.*, 2004).

The size-dependent crystallochemical behavior of RE ions in BaTiO₃ is well reproduced by atomistic simulations especially if the formation of defect clusters driven by the electrostatic interaction between the foreign ion and the oppositely charged compensation defect is taken into account (Buscaglia *et al.*, 2001; Freeman *et al.*, 2011). Both experimental results (Jonker and Havinga, 1982; Chan *et al.*, 1986; Shaikh and Vest, 1986) and simulations indicate that the preferred compensation defects in donor-doped BaTiO₃ are titanium vacancies rather than barium vacancies.

A rapid depression of the Curie point is observed even for moderate amounts of RE³⁺. The replacement of Ba²⁺ by La³⁺, Pr³⁺ and Ce³⁺ causes a lowering of T_C at a rate of 22–24°C/at% (Lu *et al.*, 2014; Morrison *et al.*, 1999; Hwang and Han, 2001a). Incorporation of Nd³⁺ determines an even faster drop of 40°C/at% (Shaikh and Vest, 1986). However, on further reducing the ionic radius of the lanthanide, both the T_C drop rate and the solubility decrease, as observed for Gd³⁺ (Ben and Sinclair, 2011). The substitution of Ho³⁺ and Er³⁺ at the Ti site results in a lowering of T_C of 17.5 and 22.2°C/at% (Liu and West, 2009; Hwang and Han, 2001b), respectively.

The incorporation of RE³⁺ ions with intermediate size (the so-called “magic” dopants, in particular Y³⁺, Dy³⁺ and Ho³⁺) in BaTiO₃ ceramics is essential to prevent the degradation of insulating resistance and strongly improves the lifetime of MLCCs with Ni electrodes fabricated by the base-metal technology (Sakabe *et al.*, 2002; Kishi *et al.*, 2003; Mizuno *et al.*, 2007). The site occupancy of these lanthanide ions was effective for controlling the donor/acceptor dopant ratio and the microstructure. The detailed mechanism is still debated, but the amphoteric nature of the dopants certainly plays an important role.

Homovalent Substitution

BaTiO₃ forms extensive solid solutions with a number of perovskites such as CaTiO₃, SrTiO₃, PbTiO₃, BaSnO₃, BaZrO₃, BaHfO₃ and BaCeO₃ (Jaffe *et al.*, 1971; Acosta *et al.*, 2017) thus allowing the modification of phase transition temperatures, polar order and properties over a broad range of compositions.

BaTiO₃-MTiO₃ solid solutions ($M = \text{Ca, Sr, Pb}$)

Despite a similar chemical behavior, Ca^{2+} and Sr^{2+} incorporated at the Ba site have a somewhat different effect on the phase transitions (Fig. 8) and properties of barium titanate which can be ascribed to their different size (Vendik and Zubko, 2000; Levin *et al.*, 2013; Fu *et al.*, 2008). The $\text{Ba}_{1-x}\text{Sr}_x\text{TiO}_3$ (BST) solid solution shows a continuous and almost linear decrease of T_C and c/a ratio with increasing x , until the quantum paraelectric (or incipient ferroelectric) behavior typical of SrTiO_3 is achieved ($x > 0.95$) (Jaffe *et al.*, 1971; Vendik and Zubko, 2000; Levin *et al.*, 2013). In contrast, in $\text{Ba}_{1-x}\text{Ca}_x\text{TiO}_3$ (BCT) both T_C and c/a ratio first show a modest increase with a maximum at $x \approx 0.10$ and then decrease though they remain close to the values of BaTiO_3 (Jaffe *et al.*, 1971; Levin *et al.*, 2013; Fu *et al.*, 2008). The maximum solubility of Ca^{2+} corresponds to $x = 0.33$. Because of its smaller ionic radius ($r^{\text{XII}} = 1.34 \text{ \AA}$) in comparison to Ba^{2+} ($r^{\text{XII}} = 1.61 \text{ \AA}$), Ca^{2+} moves off-center, as revealed by EXAFS, first-principle calculations and atomistic modeling (Levin *et al.*, 2013; Fu *et al.*, 2008; Dawson *et al.*, 2014). Furthermore, the Ca^{2+} displacement amplifies the ferroelectric off-centering of Ti cations nearest to the Ca^{2+} site in a cooperative process thus enhancing ferroelectricity despite the unit cell volume decreases. Opposite, the position of Sr cations ($r^{\text{XII}} = 1.44 \text{ \AA}$) in BST is largely central. The temperatures of the O/T and R/O transitions decrease more rapidly in BCT than in BST with increasing x , showing a strong nonlinear behavior and determining the stabilization of the T phase at low temperatures. Despite its conspicuous ionic radius in octahedral coordination ($r^{\text{VI}} = 1 \text{ \AA}$), Ca^{2+} behaves as an amphoteric dopant and substitutes Ti^{4+} up to $x = 0.04$ in $\text{BaCa}_x\text{Ti}_{1-x}\text{O}_{3-x}$ causing the suppression of T_C at a rate of $22^\circ\text{C/at\%}$ (Han *et al.*, 1987; Zhang *et al.*, 2007).

While Ca^{2+} doping at the Ba site results only in a modest increase ($8\text{--}10^\circ\text{C}$) of T_C , the incorporation of Pb^{2+} determines a continuous rise of the Curie temperature up to 490°C , the T_C of PbTiO_3 (Jaffe *et al.*, 1971). Divalent lead ions tend to move off-center the PbO_{12} dodecahedron (Sághi-Szabó *et al.*, 1999) due to the stereochemically active $6s^2$ electron lone pair and, consequently, they contribute to the overall polarization and enforce the ferroelectricity of BaTiO_3 .

MgTiO_3 crystallizes with the ilmenite-type structure and Mg^{2+} preferentially substitutes at the Ti site because of its small ionic radius ($r^{\text{VI}} = 0.72 \text{ \AA}$) up to a maximum solubility of $\approx 2 \text{ at\%}$ (Su and Button, 2004). Accordingly, it is largely used as an acceptor in the fabrication of MLCCs and promotes the formation of core-shell grains (Kishi *et al.*, 1999; Kim *et al.*, 2008; Yoon *et al.*, 2009).

BaTiO₃-BaMO₃ solid solutions ($M = \text{Sn, Zr, Hf, Ce}$)

Despite the large variation of ionic radius (Sn^{4+} : $0.69 \text{ \AA}$, Zr^{4+} : $0.72 \text{ \AA}$, Ce^{4+} : $0.87 \text{ \AA}$) of cations substituting Ti^{4+} ($0.605 \text{ \AA}$), the $\text{BaM}_x\text{Ti}_{1-x}\text{O}_3$ ($M = \text{Sn, Hf, Zr, Ce}$) solid solutions exhibit a very similar behavior of the phase transitions (Shvartsman and Lupascu, 2012; Dobal *et al.*, 2001; Simon *et al.*, 2004; Dong *et al.*, 2012; Lei *et al.*, 2007; Anwar *et al.*, 2007; Li *et al.*, 2016; Canu *et al.*, 2018), exemplified by the $\text{BaZr}_x\text{Ti}_{1-x}\text{O}_3$ (BZT) phase diagram (Dong *et al.*, 2012) shown in Fig. 9. With increasing x , the T/C

Fig. 9 Phase diagram of $x\text{BaZrO}_3-(1-x)\text{BaTiO}_3$ ceramics with $0 \leq x \leq 0.20$. Reprinted from ref. Dong, L., Stone, D.S., Lakes, R.S., 2012. Enhanced dielectric and piezoelectric properties of $x\text{BaZrO}_3-(1-x)\text{BaTiO}_3$ ceramics. *Journal of Applied Physics* 111, 084107, with the permission of AIP Publishing.

transition shifts to lower temperature while the O/T and R/T transitions move to higher temperature until they meet at the phase convergence point (x_p , T_p), giving rise to the so-called “pinched” transition. The value of x_p , 0.09–0.11, is nearly independent of specific M^{4+} cation, though some papers report $x_p \approx 0.15$ in BZT. In contrast, T_p increases with increasing the ionic radius of M^{4+} , from $\approx 320\text{K}$ (Sn) to $\approx 390\text{K}$ (Ce). When $x > x_p$, a direct and diffuse R/C transition is observed. Although the Curie temperature is depressed in comparison to undoped BaTiO_3 , the rate at which T_C decreases with increasing x depends on the size of the M^{4+} cations as shown in Fig. 10. A rapid and linear drop is observed for Sn^{4+} substitution while Ce^{4+} substitution determines a strong nonlinear behavior characterized by a decrease of T_C of only a few degrees up to $x = 0.05$ and a more rapid decay above $x = 0.10$ (Canu *et al.*, 2018). The behavior of Zr^{4+} is intermediate between Sn^{4+} and Ce^{4+} . All the considered tetravalent cations are significantly bigger than Ti^{4+} and, consequently, they have no tendency to move off-center and do not promote ferroelectric ordering. Therefore, in the case of Sn^{4+} , the linear decrease of T_C can be interpreted as a result of the dilution effect caused by the SnO_6 octahedra. However, Ce^{4+} is much bigger than Ti^{4+} and the CeO_6 octahedra are likely to determine a significant deformation and expansion of the surrounding TiO_6 octahedra enhancing the off-center displacement of Ti^{4+} and thus counterbalancing the dilution effect for low values of x (Canu *et al.*, 2018).

When the amount of M is large enough, $x = 0.19\text{--}0.22$ (≈ 0.25 for BZT), a ferroelectric to relaxor crossover occurs. In the relaxor state the average crystal structure is cubic $Pm\bar{3}m$ though at local scale it is still acentric in agreement with the existence of polar nanoregions, as discussed in Section “Phase Transition Engineering”.

Dielectric Properties

The relative dielectric constant (real part of the dielectric permittivity), ϵ' , of tetragonal BaTiO_3 single crystal is strongly anisotropic, ≈ 250 along the c -axis and ≈ 4500 on the a - b plane (Fig. 2) at room temperature. Discontinuities of ϵ' and spontaneous polarization (P_s) accompanied by hysteretic behavior are observed at the transition temperatures (Jaffe *et al.*, 1971; Mertz, 1949). The discontinuities indicate that the transitions are first-order. In ceramics these dielectric anomalies transform in peaks and the room temperature dielectric constant varies between 1000 and 5000 depending on processing, residual porosity, non-stoichiometry and grain size. The dependence of the dielectric response of BaTiO_3 ceramics on the Ba/Ti ratio was investigated by Lee *et al.* (2001). The dielectric constant attains maximum values for nearly stoichiometric compositions. In Ti-excess ceramics the permittivity drops because of the formation of a titania rich layer at the grain boundaries or $\text{Ba}_6\text{Ti}_{17}\text{O}_{40}$ inclusions. In Ba-excess samples, the decrease of the dielectric constant was ascribed to the formation of Ba_2TiO_4 inclusions and the accumulation of stress around the secondary phase particles due to the different thermal expansion in comparison to BaTiO_3 (Lee *et al.*, 2007a, 2001). In any case, the above permittivity values are 100–500 times higher than those of alumina ceramics ($\epsilon' \approx 10$), common dielectrics largely used for insulating substrates. Barium titanate also shows relatively low values ($\approx 1\%$) of the loss tangent ($\tan \delta = \epsilon''/\epsilon'$, where ϵ'' is the imaginary part of permittivity), an indispensable requirement for a dielectric to be used in capacitors (Kishi *et al.*, 2003; Pan and Randall, 2010). Despite these promising properties, the permittivity of neat barium titanate strongly depends on

temperature and the material is not suitable for most practical applications, for which a higher thermal stability of the dielectric constant and, hence, capacitance, are desired.

The above limitations were overcome by modifying the composition and the microstructure of the material and nowadays ceramic BaTiO_3 is the most widely used dielectric material in the electronic industry (Kishi *et al.*, 2003; Pan and Randall, 2010), mainly for the fabrication of MLCCs. Barium titanate ceramics belong to Class II dielectrics with dielectric constant from 1000 to > 20000 and losses in the range 0.01–0.03 (Pan and Randall, 2010). The Electronic Industry Alliance (EIA) specification of Class II dielectrics is based on a three-character alphanumeric code. In Table 1, the first character is the low temperature operating limit, the second the high temperature limit, and the third the maximum capacitance deviation over the specified temperature range. For example, X7R means that the capacitance variation is less than $\pm 15\%$ (from its value at 25°C) between -55 and 125°C . Some commonly used MLCCs have specifications Z5U, Y5V and XNR ($N = 5-8$). The temperature dependence of permittivity can be adapted to fulfill the requirements corresponding to the given specification by two main strategies: (1) engineering the phase transitions and (2) controlling the microstructure.

Phase Transition Engineering

The incorporation of foreign ions in the BaTiO_3 lattice not only determines a shift of the phase transition temperatures as discussed in detail in Section “Strategies for Modifying Defect Chemistry, Phase Transitions and Properties” but also modifies the order of the phase transition, the width of the dielectric peak at the Curie temperature, the polar order and the frequency dispersion of permittivity. The progressive shift and broadening of the permittivity peak in $\text{BaSn}_x\text{Ti}_{1-x}\text{O}_3$ as shown in Fig. 11(a) is a representative

Fig. 11 (a) Temperature dependence of the relative dielectric constant (ϵ') of BaTi_{1-x}Sn_xO₃ ($x = 0, 0.06, 0.12, 0.18, 0.24, 0.30$) ceramics at 100 kHz. Composition $x = 0.12$ is close to the phase convergence point. (b) Temperature dependence of the real (ϵ') and imaginary parts (ϵ'') of the dielectric permittivity of ceramic with composition $x = 0.30$. Reprinted from ref. Lei, C., Bokov, A.A., Ye, Z.-G., 2007. Ferroelectric to relaxor crossover and dielectric phase diagram in the BaTiO₃-BaSnO₃ system. Journal of Applied Physics 101, 084105, with the permission of AIP Publishing.

example. In many heterovalent- and homovalent-substituted BaTiO₃ ceramics the dielectric behavior gradually evolves with increasing dopant concentration and a crossover to relaxor state is often observed beyond a critical dopant concentration (Shvartsman and Lupascu, 2012). The relaxor state exists in many lead-free and lead-bearing ferroelectric systems and its typical signature is the appearance of a strong frequency dispersion of the permittivity peak temperature (T_m). The maximum of both real and imaginary part of permittivity shifts at higher temperature with increasing frequency. However, the frequency dispersion is on the low-temperature side of $\epsilon'(T)$ whereas it is on the high-temperature side of $\epsilon''(T)$ (see Fig. 11(b) as an example). The frequency dependence of T_m obeys the Vogel-Fulcher law (Shvartsman and Lupascu, 2012). Relaxor behavior is attributed to the existence of polar nanodomains or polar nanoregions (PNRs) inside a highly polarizable matrix (Shvartsman and Lupascu, 2012; Burns and Dacol, 1983; Samara, 2003). The orientation of the elemental electrical dipoles, associated to the off-center displacement of the Ti⁴⁺ ions in the TiO₆ octahedra in the case of BaTiO₃-based relaxors, is highly correlated inside each nanodomain but the dipole moments of the PNRs are almost randomly oriented. The PNRs have a size of the order of a few nanometers and are highly responsive to electric fields as indicated by slim, nonlinear $P(E)$ loops. For sufficiently high fields the nanodomains can be oriented with the electric field leading to large polarization but, on removing the field, due to thermal fluctuations most nanodomains re-acquire a random orientation resulting, differently from conventional ferroelectrics, in a very small P_r . The small but nonzero P_r indicates that a weak correlation also exists among nanodomains. It should be stressed that there is no phase transition across T_m in a relaxor, indeed the PNRs exist at much higher temperatures than T_m , up to the so-called Burns temperature, T_d (Burns and Dacol, 1983). The permittivity maximum is simply a manifestation of the slowing down of dipolar motion below T_m (Samara, 2003). The average structure of a perovskite relaxor is usually cubic but at local level the spatial symmetry is broken, as indicated by Raman scattering and PDFs analysis (Hou et al., 2018). The existence of PNRs becomes apparent even in the absence of an electric field on properties depending on P^2 , for example in the deviation of the temperature dependence of refractive index and thermal expansion below T_d from the

behavior predicted for the paraelectric state (Burns and Dacol, 1983; Samara, 2003). At sufficiently low temperature (T_f), the dipolar motion freezes and the permittivity dispersion vanishes.

The dielectric properties of two families of BaTiO₃ solid solutions, BaM_xTi_{1-x}O₃ and BaTiO₃-Bi(M)O₃, which have attracted attention for application in capacitors will be discussed in some detail.

BaTiO₃-BaMO₃ solid solutions

In the case of BaM_xTi_{1-x}O₃ (M = Sn, Zr, Hf, Ce) solid solutions (Lei *et al.*, 2007; Canu *et al.*, 2018; Hennings *et al.*, 1982; Hansen *et al.*, 1998; Shvartsman *et al.*, 2009, 2008; Gao *et al.*, 2017; Kleemann *et al.*, 2013; Maiti *et al.*, 2008), the phase transition sequence (see Fig. 9 as an example), the polar order and the dielectric properties (Fig. 11) change according to the following scenario:

- (1) In the BaTiO₃-rich side of the system, T_C decreases with increasing x whereas the R/O and O/T transition temperatures rise until the three transitions merge at the phase convergence point (x_p, T_p) with $x_p \approx 0.10$, as described above. For small values of x not larger than a few at%, the T/C transition remains sharp and first order as in neat BaTiO₃. For larger x values, the permittivity peak at T_C broadens and at x_p the transition changes to second order.
- (2) The dielectric constant attains its maximum value at or close to x_p . The peak permittivity can be very high, of the order of a few tens of thousands. BZT ceramics, further modified by partial substitution of Ca at the Ba site, have maximum relative permittivity of ≈ 30000 around room temperature and a moderate temperature stability suitable for Z5U and Y5V capacitors (Hennings *et al.*, 1982; Hansen *et al.*, 1998).
- (3) For $x > x_p$, only a single R/C transition persists. The transition becomes progressively more diffuse in temperature (DPT, diffuse phase transition) as indicated by the appearance of a broad and rounded permittivity peak accompanied by some frequency dispersion. Despite the smearing of the transition, the temperature corresponding to the permittivity maximum (T_m) remains independent of frequency and can still be identified as the average T_C .
- (4) Beyond a certain substitution level x_r ($x_r = 0.20$ – 0.25 depending on M), the value of T_m starts to move at higher temperatures with increasing frequency, a typical sign of relaxor behavior. The ferroelectric to relaxor crossover occurs over a finite composition range and is not accompanied by a macroscopic phase transition (Shvartsman and Lupascu, 2012; Kleemann *et al.*, 2013). Recent broad-band dielectric spectroscopy investigations have suggested that BaZr_xTi_{1-x}O₃ compositions, especially those with $x \geq \approx 0.50$ behave like a dipolar glass rather than a typical relaxor (Filipič *et al.*, 2016; Petzelt *et al.*, 2014). Furthermore, ferroelectric order could not be induced by the application of an electric field for the composition with $x = 0.50$. The dielectric relaxation is assigned to local hopping of the off-centered Ti⁴⁺ ions in frozen BaTiO₃ clusters, whose size is rather small and cannot grow on cooling (Petzelt *et al.*, 2014).
- (5) Relaxor or dipolar glass behavior persists up to values of x very close to 1 when M = Zr as complete solid solubility exists between BaTiO₃ and BaZrO₃ (Maiti *et al.*, 2008). BaZrO₃ is a paraelectric solid with a relative dielectric constant of 37–38 at room temperature and cubic $Pm\bar{3}m$ structure up to the melting point (Akbarzadeh *et al.*, 2005). Complete solid solubility with BaSnO₃ and BaHfO₃ is also likely. In contrast, the maximum solubility of BaCeO₃ is limited and corresponds to $x = 0.33$ – 0.35 (Makovec *et al.*, 1996; Lu *et al.*, 2012).

The evolution of polar order and the decrease of dipole correlation length with composition in BaZr_xTi_{1-x}O₃ is well supported by Raman spectroscopy studies (Dobal *et al.*, 2001; Miao *et al.*, 2009; Buscaglia *et al.*, 2014). Strong Raman bands not compatible with a cubic structure were revealed for the relaxor composition $x = 0.40$ but cannot be attributed to a specific symmetry and no sign of phase transitions was detected in the range 78–398 K. The persistence of some polar bands in the Raman spectra (Buscaglia *et al.*, 2014, 2006a) far above the ferroelectric–paraelectric transition as well as measurements of acoustic emission (Dul'kin *et al.*, 2010) and refractive index (Burns and Dacol, 1982) support the existence of locally correlated displacements on the Ti sites and of polar clusters in undoped BaTiO₃ and BZT compositions $x = 0.10$ – 0.20 (Shvartsman and Lupascu, 2012). However, the dynamics of these polar clusters if compared to conventional relaxors, is much faster, reaching the THz range, and the dielectric anomaly at T_C is frequency independent in the radiofrequency region (Dul'kin *et al.*, 2010).

The local structure and polar order of BZT has been carefully investigated using X-ray absorption fine structure (XAFS) measurements as well as X-ray and neutron PDF analysis (Buscaglia *et al.*, 2014; Laulhe *et al.*, 2009; Levin *et al.*, 2011). The PDF provides direct evidence that the Ti and Zr atoms do not occupy the equivalent octahedral sites expected from the average cubic crystallographic structure of the solid solution. Because of the relatively large difference between the ionic radii of Zr⁴⁺ and Ti⁴⁺, the TiO₆ and ZrO₆ octahedra have a tendency to preserve their individuality, i.e. despite a broad bond length distribution, the average value of the Ti–O and Zr–O distances are, for most of the compositional range, similar to those observed in BaTiO₃ and BaZrO₃, respectively (Laulhe *et al.*, 2009; Levin *et al.*, 2011). This is evident in the neutron PDF because the neutron scattering factor of Ti is negative whereas those of the other involved elements is positive. This produces a “negative” peak for the Ti–O pair and a positive peak of the Zr–O pair (Laulhe *et al.*, 2009), as shown in Fig. 12. Furthermore, the X-ray PDF studies (Buscaglia *et al.*, 2014) suggest that the local structure of Ti-rich compositions is always rhombohedral with Ti displacement in the [111] pseudocubic direction, including the relaxor composition $x = 0.40$ which exhibited a cubic $Pm\bar{3}m$ diffraction pattern (from high-resolution synchrotron radiation experiments) at 100–450 K.

XAFS measurements of Levin *et al.* (2011) have revealed that for low concentrations of Ti, isolated Ti atoms in the relatively large octahedral sites of the BaZrO₃ lattice acquire centrosymmetric coordination with average Ti–O distances shorter than those in BaTiO₃. In contrast for higher concentrations of titanium, Ti atoms having one or more Ti as their B-site nearest neighbors undergo

Fig. 12 Experimental pair distribution function of (a) BaZrO₃, (b) BaTiO₃, and (c) BaTi_{0.68}Zr_{0.32}O₃ at 300K (crosses), compared with the PDF calculated from their crystallographic structures (lines). Inset in figure (b): zoom on the contribution of the Ti-O pairs within the TiO₆ octahedra in BaTiO₃. Reprinted figure with permission from ref. Laulhé, C., Hippert, F., Bellissent, R., Cuello, G.J., 2009. Local structure in BaTi_{1-x}Zr_xO₃ relaxors from neutron pair distribution function analysis. *Physical Review B* 79, 064104. Copyright (2009) by the American Physical Society.

polar off-center displacements. Opposite, Zr cations are essentially in centric position. Significant deviations from a random distribution of Ti and Zr (i.e., segregation phenomena) were not detected except for compositions close to BaTiO₃.

The local structure of BaTi_{0.74}Zr_{0.26}O₃ was investigated via first-principle calculations using $3 \times 3 \times 3$ supercells (Laulhé *et al.*, 2010). While Ba and Zr off-center displacements were small and uncorrelated, Ti off-center displacement was of the same magnitude as in BaTiO₃. Notably, the direction of a Ti-atom displacement is variable and entirely determined by the distribution of the Ti and Zr atoms in the adjacent unit cells. The underlying mechanism involves local strain effects that ensue from the difference in size between the Ti⁴⁺ and Zr⁴⁺ cations. A Ti atom is no longer displaced in the direction in which its octahedral cage is compressed.

Because of the existence of a phase convergence point, BaM_xTi_{1-x}O₃ systems are of potential interest for electrocaloric cooling. Liu *et al.* (2012) have predicted that an enhanced electrocaloric effect or, in other words, a larger temperature variation ΔT , can be attained for compositions close to the convergence point since the dipole entropy increases by increasing the number of coexisting phases which is maximum at the convergence point. Experimental verification was carried out on different systems varying the composition, x . In particular, Qian *et al.* (2014) have measured a ΔT of 4.2–4.5K for $x = 0.15$ – 0.20 in BaZr_xTi_{1-x}O₃ ceramics using an electric field of $\approx 150 \text{ kV cm}^{-1}$. In the homologous systems with Hf and Sn, the temperature variation was maximized at $x = x_p$. A significant ΔT of 0.35K was obtained in BaHf_{0.11}Ti_{0.89}O₃ under an electric field of only 10 kV cm^{-1} (Li *et al.*, 2016) and a similar result was reported for BaSn_{0.105}Ti_{0.895}O₃ (Luo *et al.*, 2014).

BaTiO₃-Bi(M)O₃ solid solutions

Solid solutions between BaTiO₃ and Bi(M)O₃ compounds, such as BiScO₃, Bi(Zn_{0.5}Ti_{0.5})O₃, Bi(Mg_{0.5}Zr_{0.5})O₃, Bi(Mg_{0.5}Ti_{0.5})O₃ and Bi(Mg_{2/3}Nb_{1/3})O₃, show a common behavior and interesting dielectric properties for high-temperature capacitor applications (Beuerlein *et al.*, 2016). When the mole fraction of Bi(M)O₃ is between 0.05 and 0.15, depending on M, a transition from tetragonal *P4mm* to a pseudocubic structure is observed. Although the average structure appears cubic at X-ray and neutron diffraction, a detailed refinement performed on the (1-*x*)BaTiO₃-*x*Bi(Zn_{0.5}Ti_{0.5})O₃ compositions (*x* = 0.10, 0.20) shows that the oxygen ions and B-site cations (Ti, Zn) are displaced from the positions of the cubic perovskite lattice. PDF analysis indicates that the local structure (1–10 Å) is better described by a *P4mm* model with a *c/a* ratio of 1.014 (*x* = 0.20), close to that of BaTiO₃. However, the *c/a* ratio decreases with increasing the scale length. Beyond 3–4 nm, the structure is very close to the cubic one. The correlation between the atomic displacements is gradually lost with increasing distance and beyond a scale length corresponding to 6–8 unit cells the distortions will be almost averaged out. The introduction of Bi(Zn_{0.5}Ti_{0.5})O₃ (*x* ≥ 0.10) in the BaTiO₃ lattice introduces sufficient chemical and compositional disorder to break the long-range ferroelectric order. In contrast, for compositions *x* = 0.06 and 0.08, both the average and local structure are tetragonal although at short scale lengths (< 2 nm) the *c/a* ratio is higher than that of the average structure. The PDF analysis gives direct evidence of the existence of polar clusters for all compositions up to at least 225°C (Hou *et al.*, 2017), a temperature much higher than the Curie point of BaTiO₃.

Solid solutions with composition in the pseudocubic region exhibit relaxor behavior and a very broad permittivity peak with stable permittivity over a wide temperature range (Zeb and Milne, 2015; Ogihara *et al.*, 2009; Xiong *et al.*, 2011; Zeb and Milne, 2014a,b). The addition of Bi(M)O₃ amounts around 30–50 mol% broadens the stability range up to temperatures > 400°C as shown in Fig. 13(a). Good thermal stability at 50–350°C and 1 kHz with $\epsilon' \approx 1000$ was reported for 0.7BaTiO₃-0.3BiScO₃ although $\tan\delta$ rapidly rises above 300°C (Ogihara *et al.*, 2009). A dielectric constant of $\approx 1030 \pm 15\%$ over the temperature range 25–420°C was reported for the composition 0.7Ba_{0.8}Ca_{0.2}TiO₃-0.3Bi(Zn_{0.5}Ti_{0.5})O₃ (Zeb and Milne, 2014a) while for 0.7BaTiO₃-0.3Bi(Mg_{0.5}Zr_{0.5})O₃ ceramics ϵ' was $\approx 570 \pm 15\%$ between –20 and 430°C (Zeb and Milne, 2014b) at 1 kHz with low tangent loss (< 2%) in both cases. The temperature stability range can be further widened up to 550°C in (1-*x*)BaTiO₃-*x*Bi(Mg_{2/3}Nb_{1/3})O₃ ceramics, *x* = 0.50–0.60, (Muhammad *et al.*, 2016) while a very flat permittivity plateau of ≈ 1100 was reported for the ternary *x*BaTiO₃-(1-*x*)(0.5Bi(Zn_{1/2}Ti_{1/2})O₃-0.5BiScO₃) system (Raengthon *et al.*, 2012). Large amounts of Bi(M)O₃ often lead to inhomogeneous element distribution and formation of core-shell grains which contribute to improve the temperature stability (Ogihara *et al.*, 2009; Zeb and Milne, 2014b). Extensive formation of core-shell grains was observed in BaTiO₃-based ceramics containing only 5 mol% BiScO₃. Complete homogeneity could not be obtained even after 20 h sintering (Ogihara *et al.*, 2009).

While for the tetragonal ferroelectric phase (*x* ≤ 0.07), the Curie temperature of (1-*x*)BaTiO₃-*x*BiScO₃ ceramics decreases with increasing *x*, both *T_m* and *T_f* of compositions with pseudocubic structure (*x* > 0.07) increase with increasing *x*, though BiScO₃ is a paraelectric solid. A similar behavior was only reported for BaTiO₃-PbTiO₃ and BaTiO₃-Na_{0.5}Bi_{0.5}TiO₃ solid solutions but, in these cases, both end members are ferroelectric (Jaffe *et al.*, 1971; Datta *et al.*, 2010). A further peculiarity of the BaTiO₃-BiScO₃ system (*x* ≥ 0.10) is represented by the re-entrant relaxor behavior. By decreasing the temperature, the remanent polarization first grows from a very low level to values typical of long-range ferroelectric order and then drops again on further cooling (Bharadwaja *et al.*, 2011). This indicates that the system re-enters in a more disordered state. The maximum of remanent polarization is observed at temperatures close to *T_f*. According to Guo *et al.* (2008) and differently from most relaxors in which the PNRs emerge from the paraelectric state, polar clusters grow inside the ferroelectric matrix below *T_f*.

The Curie temperature of (1-*x*)BaTiO₃-*x*Bi(Na_{0.5}Ti_{0.5})O₃ (*x* = 0–0.30) solid solutions increased from 136°C (*x* = 0) to 214°C (*x* = 0.30) with increasing *x*. Stabilization of the tetragonal *P4mm* phase and increase of the *c/a* ratio in comparison to pure BaTiO₃ is observed over a wide temperature range, from –250°C to *T_C* (Datta *et al.*, 2010). The addition of 10% Bi(Na_{0.5}Ti_{0.5})O₃ can be used to broaden the application field of barium titanate up to 150°C. Further modification of the dielectric properties by Nb₂O₅ addition leads to ceramics with an average dielectric constant of ≈ 1600 , compatible with the X9R specification. The properties can be further modified by adding other dopants. A representative example is given in Fig. 13(b) (Chen *et al.*, 2019). Ceramics with composition (1-*x*)BaTiO₃-*x*LiTaO₃, *x* = 0.25–0.30 are also X9R compliant with ϵ' in the range 700–900 (Wang *et al.*, 2013). In addition, they can be sintered in reducing atmosphere and are, in principle, compatible with the base metal electrode technology.

In general, cofiring of Bi-containing dielectrics with base metal electrodes is quite challenging because of the reduction of Bi₂O₃ to metallic bismuth at the reduced oxygen partial pressure needed to avoid the electrode oxidation. Even cofiring with noble metal electrodes is not trivial due to the reactivity of Bi-based dielectrics and the sintering temperature has to be carefully chosen to overcome this problem (Beuerlein *et al.*, 2016).

Microstructure Control: Core-Shell Grains

Microstructure and, in particular, grain size has a strong impact on ferroelectric, dielectric and piezoelectric properties. The role of grain size has been widely investigated and will be discussed in more detail in Section “Size and Scaling Effects”. From the point of view of obtaining dielectrics with temperature-stable permittivity, a key aspect is represented by the fabrication of ceramics consisting of grains with a core-shell structure.

In general, the temperature stability can be improved by means of ceramics with non-homogeneous composition at the level of the single grains. For example, the partial interdiffusion between a BaTiO₃ core and a SrTiO₃ or BaZrO₃ shell produces grains with

a radial composition gradient and, consequently, with a distribution of the Curie temperature resulting in a broad permittivity peak (Buscaglia *et al.*, 2006c; Wu *et al.*, 2015; Airimioaei *et al.*, 2017). However, the preferred microstructure for temperature-stable dielectrics belonging to XNR (N = 6–8) classes consists of a nearly pure BaTiO₃ core surrounded by a shell of more heavily doped material (Fig. 14), characterized by diffuse phase transition or relaxor behavior with a broad permittivity peak around room temperature (Jeon *et al.*, 2012). This result can be attained by controlling the Ba/Ti ratio, the amount and distribution of an appropriate dopant oxide, and grain growth (Jeon *et al.*, 2012; Armstrong *et al.*, 1989; Hennings and Schreinemacher, 1994; Chazono and Kishi, 1999). In order to obtain reliable capacitors with improved lifetime by means of the base-metal electrode technology (Ni or Cu electrodes), at least two dopants are needed (Kishi *et al.*, 2003; Sato *et al.*, 1999). A first dopant is an acceptor (Mn²⁺, Mg²⁺, Ca²⁺, etc.) added in a small amount (1–2 at%), which substitutes at the Ti site avoiding the degradation of the dielectric properties of BaTiO₃ during sintering in a reducing atmosphere. The preferred second dopant is a rare-earth ion with intermediate ionic radius (Y³⁺, Ho³⁺, Dy³⁺), which substitutes at both Ba and Ti site and is mainly confined in the shell region (Fig. 14). These rare-earths significantly improve the capacitor lifetime, hindering the degradation of the insulation resistance and, for this reason, they are often denoted as “magic” dopants (Kishi *et al.*, 2003; Sato *et al.*, 1999). The mechanism has not fully been elucidated in detail yet but it is certainly determined by the amphoteric behavior of these ions and the resulting effective control of the acceptor/donor ratio, as discussed in Section “Incorporation of Rare-Earth Ions”. Prior to the use of rare-earth dopants, BaTiO₃-Co₃O₄-Nb₂O₅ ceramics were widely investigated and used as X7R dielectrics (Hennings and Schreinemacher, 1994; Chazono and Kishi, 1999). A sintering aid, usually a powdered glass or silica, is often added to lower the sintering temperature. In most cases, the formation of the shell does not occur by solid-state diffusion of the dopant but, rather, by a dissolution-precipitation process mediated by the existence, during sintering, of a liquid phase in which the dopant oxides dissolve (Jeon *et al.*, 2012; Chazono and Kishi, 1999; Hennings and Rosenstein, 1984; Armstrong and Buchanan, 1990; Chazono and Kishi, 2000; Kim and Kang, 1999).

Reprinted from ref. Jeon, S.-C., Lee, C.-S., Kang, S.-L., 2012. The mechanism of core/shell structure formation during sintering of BaTiO₃-based ceramics. *Journal of the American Ceramic Society* 95, 2435–2438 with permission of Wiley. Copyright (2012) American Ceramic Society.

Microstructure control plays a crucial role on the performances of the capacitors and needs the optimization of several parameters. Sintering temperature has to be carefully optimized as variations of only 10–20°C can significantly modify the dielectric properties (Chazono and Kishi, 1999; Mizuno *et al.*, 1998) by inducing grain growth and composition homogenization. The relative amount of the dopants has also a crucial influence on the temperature stability. In BaTiO₃-Co₃O₄-Nb₂O₅ dielectrics (Chazono and Kishi, 1999, 2000), the inward diffusion of Co is no longer prevented if Nb/Co < 2, resulting in composition homogenization and collapse of the core-shell structure. In BaTiO₃ ceramics co-doped with Mg and Ho, an appropriate amount of Mg is necessary for suppressing the inward diffusion of the rare-earth ions. MgO first reacts with BaTiO₃ and forms the shell region in which Mg²⁺ substitutes at the Ti site. At higher temperature, Ho³⁺ also incorporates in the perovskite but its diffusivity is controlled by the Mg/Ho ratio (Kishi *et al.*, 1997). Likewise, the Mg/Y ratio plays a dominant role in the formation of the core-shell structure in BaTiO₃-MgO-Y₂O₃ dielectrics (Kim *et al.*, 2008). In general, a higher amount of MgO is required to suppress the grain growth and the diffusion into the core region for the larger lanthanide ions (La³⁺, Sm³⁺) compared to the intermediate size ions (Ho³⁺, Dy³⁺, Er³⁺) (Kishi *et al.*, 1999). The different behavior is related to the different incorporation site of the lanthanide ions: predominant substitution at Ba site for La³⁺ and Sm³⁺, substitution at both Ba and Ti site for Ho³⁺, Dy³⁺ and Er³⁺, as discussed in Section “Incorporation of Rare-Earth Ions”. It is worth noting that in the fabrication of MLCCs, the dielectric material is prepared by directly adding the different dopants to the BaTiO₃ powder. The lanthanide ions of intermediate size distribute between the two cation sites depending on the A/B ratio. The volumetric ratio between core and shell is also an important microstructural parameter.

A better control on the formation of the core-shell structure, especially when the grain size is in the submicron scale, can be achieved by coating the BaTiO₃ particles with a layer of the dopant oxide using a colloidal chemistry approach (Zhang *et al.*, 2011). The formation of core-shell grains is also essential to obtain X9R-compliant dielectrics (Chen *et al.*, 2019; Yao *et al.*, 2012a).

One of the main drawbacks of BaTiO₃ ceramics is the relatively low dielectric strength ($E_b \approx 90 \text{ kV cm}^{-1}$) which limits the high-field applications. A significant improvement of the breakdown field can be obtained by realizing BaTiO₃-SiO₂/glass composites with a microstructure comprising BaTiO₃ grains surrounded by a silica/glass layer at grain boundary (Zhang *et al.*, 2015;

Wang *et al.*, 2012; Liu *et al.*, 2017b; Yuan *et al.*, 2017a). Zhang *et al.* (2015) have observed a progressive increase of E_b from 90 to 280 kV cm⁻¹ with increasing silica content from 0 to 8 wt% and a parallel decrease of the dielectric constant from ≈ 4000 to ≈ 500 . The ceramics were fabricated using BaTiO₃@SiO₂ core-shell particles prepared by a Stöber-like process with different thickness of the silica shell. The existence of a continuous silica network with a low dielectric constant (≈ 4) determines a strongly nonhomogeneous distribution of the electric field. In particular, the electric field in the silica layer is higher than the applied field, whereas it is lower than the applied field in the ferroelectric cores. The higher dielectric strength of silica (≈ 400 kV cm⁻¹) and the “screening” effect of the shell results in improved insulating properties of the composite. The breakdown field further increases to ≈ 330 kV cm⁻¹ in BaTiO₃/BaTiO₃@SiO₂/BaTiO₃ multilayered thick films (Yuan *et al.*, 2017a).

The encapsulation of BaTiO₃ and Ba_{0.6}Sr_{0.4}TiO₃ particles of different diameter with an amorphous silica shell by means of a modified Stöber process, using tetraethoxysilane (TEOS) as precursor, was investigated by Elissalde *et al.* (Hornebecq *et al.*, 2004; Mornet *et al.*, 2005; Chung *et al.*, 2009, 2010). In the case of Ba_{0.6}Sr_{0.4}TiO₃ particles, the thickness of the shell can be controlled between 2 and 80 nm with high accuracy (Mornet *et al.*, 2005). Thanks to the silica shell, the sintering temperature can be decreased to $\approx 1000^\circ\text{C}$, in comparison to values of the order of 1300–1400°C required for the uncoated particles, thus avoiding grain growth. Good densification (92%) was also obtained by sintering in a microwave furnace (Chung *et al.*, 2010). Densification of BaTiO₃@SiO₂ core-shell particles by Spark Plasma Sintering and post-annealing at 800°C in air produced ceramics with a giant dielectric constant ($> 10^5$, 10 kHz) and a relatively low loss tangent (≈ 0.05) in the range 25–180°C (Chung *et al.*, 2009). The silica shell is a good dielectric and, moreover, slows down reoxidation of the inner region of the BaTiO₃ grains, which remain semiconducting after post-annealing. At low frequency ($< 10^5$ Hz) and above room temperature, the effective permittivity is controlled by the insulating grain boundary layer, whereas at higher frequency and lower temperature the contribution of grain cores predominates and the permittivity drops to values typical of BaTiO₃.

Dielectrics for Energy Storage

The main driving force for the continuous development of the MLCC technology is the large scale application of these passive components in consumer electronics. However, in the last few years there has been an increasing demand for ceramic capacitors with higher energy density for power electronic devices and pulse power applications, including hybrid and electrical vehicles. While ceramic capacitors have a high power density (fast charge/discharge performances), the energy density is relatively low and extensive studies have been undertaken to develop new dielectric materials with enhanced breakdown field and improved storage efficiency (Yao *et al.*, 2017; Palneedi *et al.*, 2018; Prateek *et al.*, 2016).

Room-temperature properties of some bulk ceramics reported in recent years (Ogihara *et al.*, 2009; Yuan *et al.*, 2018, 2017b; Zhou *et al.*, 2018; Yang *et al.*, 2017; Li *et al.*, 2017; Wang *et al.*, 2015; Wu *et al.*, 2016; Shen *et al.*, 2015; Song *et al.*, 2014, 2015; Huang *et al.*, 2015; Yang *et al.*, 2018) are summarized in Table 2. Because of the slim polarization loops (small hysteresis) and high breakdown field, BaTiO₃-Bi(M)O₃ relaxors are potential dielectric materials for energy storage. The recoverable energy density attains values up to 2–3 J cm⁻³ with efficiency of 80%–90% at fields of ≈ 200 kV cm⁻¹. Thin (15 μm thickness) BaTiO₃-BiScO₃ dielectrics exhibited superior energy storage capability at the same applied electric field, relative to commercial MLCCs (Ogihara *et al.*, 2009). The charge storage performance of BaTiO₃ ceramics is significantly lower (energy density: 0.3–0.4 J cm⁻³), because of the large hysteresis (efficiency $< 50\%$) and the inferior dielectric strength (≈ 90 kV cm⁻¹) (Zhang *et al.*, 2015; Wang *et al.*, 2012). However, the recoverable energy density can substantially be increased up to 1.2 J cm⁻³ in ceramics obtained by densification of BaTiO₃@SiO₂ core-shell particles (Zhang *et al.*, 2015), because of the enhanced dielectric strength, as previously discussed.

BaTiO₃-Bi(M)O₃ relaxors also exhibit excellent thermal stability of the energy density and efficiency. Ceramics with composition 0.85BaTiO₃-0.15Bi(Mg_{0.5}Zr_{0.5})O₃ show a decrease of energy density of only 12% from room temperature to 150°C at a field of 220 kV cm⁻¹ and energy efficiency $> 80\%$ (Yuan *et al.*, 2018). A similar stability was reported for 0.85BaTiO₃-0.15Bi(Zn_{1/2}Sn_{1/2})O₃ at 150 kV cm⁻¹, with an efficiency $> 95\%$ (Zhou *et al.*, 2018).

Ba_{1-x}Sr_xTiO₃ ceramics (Song *et al.*, 2014, 2015; Huang *et al.*, 2015; Yang *et al.*, 2018) in the paraelectric state at room temperature also show significantly enhanced energy storage density in comparison to BaTiO₃ (up to 1.3 J cm⁻³, Table 2) though the performances are inferior to the previously described BaTiO₃-based relaxors.

Tunable Dielectrics

Only a few remarks on BaTiO₃-based tunable dielectrics will be given here; for a detailed overview on tunable ferroelectrics the review paper of Tagantsev *et al.* (2003) is recommended. A typical feature of ferroelectric materials is the strong nonlinear dependence of dielectric permittivity on the applied bias electric field. This feature is described by the tunability, n , the ratio of the permittivity of the material at zero electric field, $\epsilon'(0)$, to the permittivity at a given non-zero electric field, $\epsilon'(E)$. The relative tunability is defined as $[\epsilon'(0) - \epsilon'(E)]/\epsilon'(0)$ (Tagantsev *et al.*, 2003). A variable permittivity with high tunability is attractive for the fabrication of microwave devices such as tunable dielectric resonators, tunable filters and tunable capacitors (varactors). However, the higher losses of ferroelectrics in comparison to conventional microwave dielectrics and the high voltage needed for tuning limit the use of bulk ceramic or single crystal varactors. Materials in the paraelectric state are preferred because the absence of domains reduces the losses and the hysteretic behavior. BaTiO₃-based solid solutions such as Ba_{1-x}Sr_xTiO₃, BaTi_{1-x}Zr_xO₃ and BaTi_{1-x}Sn_xO₃ ceramics show a high tunability, especially in the vicinity of phase transitions. At room temperature, the relative

Fig. 15 (a) Dielectric permittivity vs. bias electric field and (b) relative tunability vs. temperature for different BaTi_{1-x}Zr_xO₃ ceramics ($x = 0.20-0.35$). Reprinted from ref. Tang, X.G., Chew, K.-H., Chan, H.L.W., 2004. Diffuse phase transition and dielectric tunability of Ba(Zr_yTi_{1-y})O₃ relaxor ferroelectric ceramics. *Acta Materialia* 52, 5177–5183, with permission from Elsevier. Copyright (2004) Acta Materialia Inc.

tunability at 30 $kV\ cm^{-1}$ and 10 kHz is 80% for BaZr_{0.25}Ti_{0.75}O₃ and 50% for Ba_{0.60}Sr_{0.40}TiO₃ (Zhang *et al.*, 2012). The variation of permittivity with dielectric field and of relative tunability with temperature is reported in Fig. 15 for different BaTi_{1-x}Zr_xO₃ compositions ($x = 0.20-0.35$). Compositions $x = 0.20$ and 0.25 show the maximum relative tunability (85%) at the Curie temperature (297K and 257K, respectively) (Tang *et al.*, 2004). Compositions $x = 0.30$ and 0.35 have a relaxor behavior. For many homogeneous single phase ferroelectrics, the higher the permittivity the higher the tunability but also the losses and the temperature dependence of permittivity (Tagantsev *et al.*, 2003). The correlation between tunability and losses obliges to find materials with the best trade-off between these two parameters. A guide to choose among different materials is provided by the commutation quality factor (Tagantsev *et al.*, 2003). Given an appropriate value of the quality factor required for the specific application, materials with high tunability ($n \geq 1.5$) and not too high permittivity (≤ 1000) are generally preferred. Composites between Ba_{1-x}Sr_xTiO₃ and a linear dielectric oxide, such as MgO, have been extensively investigated because the dielectric constant can be adjusted and losses lowered by changing the amount of the linear dielectric while retaining a reasonable tunability (Tagantsev *et al.*, 2003; Zhang *et al.*, 2012; Chang and Sengupta, 2002; Chung *et al.*, 2008).

Piezoelectric Properties

BaTiO₃ was the first oxide material to be developed as a piezoceramic (Randall *et al.*, 2004; Jaffe *et al.*, 1971; Haertling, 1999) and was used on large scale for applications in the generation of acoustic and ultrasonic vibrations, vibration detection and actuators. Typical values of the piezoelectric properties of BaTiO₃ ceramics are $d_{33} = 191$ pC/N, $d_{31} = -79$ pC/N, $d_{15} = 270$ pC/N, $k_{33} = 0.49$, $k_p = 0.38$ (Jaffe *et al.*, 1971). The piezoelectric properties of BaTiO₃, likewise dielectric permittivity, are strongly temperature dependent because of the polymorphic transitions. For most commercial purposes it is now superseded by Pb(Zr,Ti)O₃ (PZT) ceramics, with morphotropic boundary composition. PZT has superior properties, a wider temperature application range and a higher thermal stability. Undoped BaTiO₃ cannot be used for high field and high frequency applications such as the generation of ultrasonic power, because of the rapid increase of dielectric losses with increasing field. These losses arise largely from the movement of domain walls. Substitution of transition metal ion acceptors (Co^{3+} is particularly effective) at the Ti site leads to domain wall clamping and consequently to a strong reduction of the losses. As a further effect of domain wall clamping, Co^{3+} -doped BaTiO₃ shows greater resistance than PZT to depoling by compressive stresses and, consequently, it is still used in some applications despite the inferior piezoelectric activity (Jaffe *et al.*, 1971; Moulson and Herbert, 1990). The piezoelectric properties of barium titanate ceramics can be further modified by tailoring the microstructure. The influence of grain size will be discussed in Section “Size and Scaling Effects”.

In recent years, BaTiO₃-based piezoceramics have attracted a renewed interest after the publication of the paper of Liu and Ren (2009) in 2009, reporting outstanding piezoelectric properties, comparable or even superior to those of PZT at room temperature, in the $(1-x)\text{Ba}(\text{Ti}_{0.8}\text{Zr}_{0.2})\text{O}_{3-x}(\text{Ba}_{0.7}\text{Ca}_{0.3})\text{TiO}_3$ system (BCTZ) for $x = 0.50$. The material showed $d_{33} \approx 600$ pC N⁻¹ and a large signal piezoelectric coefficient d_{33}^* (defined as the ratio of the strain and the corresponding electric field) of 1140 pm V⁻¹ at 50 kV cm⁻¹. An even higher value of d_{33}^* of 1310 pm V⁻¹ at 50 kV cm⁻¹ was reported at $x = 0.45$ by Ehmke *et al.* (2012). The high piezoelectric activity was initially attributed to the existence of a morphotropic phase boundary (MPB) between the tetragonal and the rhombohedral phase. However, Keeble *et al.* (2013), in 2013, on the basis of a careful temperature dependent XRD study of this system, demonstrated that there is not a MPB but, rather, a narrow temperature-composition region, which separates the other two crystallographic polar variants, where the orthorhombic phase is stable (see Fig. 16). A phase diagram very similar to that reported in Keeble *et al.* (2013) was constructed by Acosta *et al.* (2014) from dielectric permittivity data. Moving from low to high temperature, the same phase sequence (R-O-T-C) as in undoped BaTiO₃ is observed. However, as the presence of Zr lowers the T_C and stabilizes the R phase at higher temperature, while the effect of calcium is to shift the R/O and O/T boundaries at lower temperature, the three phase transitions are observed in a narrow (270–365 K) temperature range at $x = 0.50$. Furthermore, the different transitions meet at a phase convergence point at $x = 0.32$ – 0.35 and 333 – 337 K. The phase boundaries are not horizontal but quite slanting, this enhances the tendency to “instability” of the system, a situation quite favorable for producing high piezoelectric properties. In fact, small variations of composition or temperature stabilize one phase respect to the adjacent one, meaning that the free energy landscape is rather flat, thus promoting phase coexistence, increasing the degrees of freedom of the system and making it highly responsive to external stimuli. One possible mechanism responsible for properties enhancement is the “polarization rotation” (Damjanovic, 2005) process. Available data indicate that d_{33} features maximum values around the phase transitions when varying temperature at constant composition or composition at constant temperature (Acosta *et al.*, 2017, 2014), as shown in Fig. 17. At room temperature, Zhang *et al.* (2014) reported two maxima of d_{33} corresponding to the R/O transition at $x = 0.44$ and the O/T transition at $x = 0.50$. More generally, the highest values of d_{33} are obtained along the O/T transition, while high values of d_{33}^* are observed over a broad region around the O phase with maximum at R/O and O/T transitions. A second maximum of d_{33} is located at $x \approx 0.35$, just above room temperature and close to the R/O transition. These features are partially inherited from the $\text{BaZr}_y\text{Ti}_{1-y}\text{O}_3$ system, which shows the same behavior for $y = 0.06$ – 0.10 , with $d_{33} = 770$ pC N⁻¹ at 65°C at the O/T transition (Dong *et al.*, 2012). This further confirms that an important effect of Ca substitution is the shift the O/T phase transition to room

Fig. 17 Contour plot of (a) small signal d_{33} and (b) large signal d_{33}^* as a function of temperature and composition in the $(1-x)\text{Ba}(\text{Zr}_{0.2}\text{Ti}_{0.8})\text{O}_{3-x}(\text{Ba}_{0.7}\text{Ca}_{0.3})\text{TiO}_3$ system. Reprinted from ref. Acosta, M., Novak, N., Jo, W., Rödel, J., 2014. Relationship between electromechanical properties and phase diagram in the $\text{Ba}(\text{Zr}_{0.2}\text{Ti}_{0.8})\text{O}_{3-x}(\text{Ba}_{0.7}\text{Ca}_{0.3})\text{TiO}_3$ lead-free piezoceramic. *Acta Materialia* 80, 48–55, with permission from Elsevier. temperature when $x = 0.50$. The origin of the large piezoelectric activity in BCTZ ceramics was investigated using the Landau-Devonshire phenomenological theory (Acosta *et al.*, 2015). Based on the combined computational and experimental results, it was concluded that a reduction in anisotropy energy (i.e., a weaker dependency of energy on the polarization orientation) accompanied by elastic softening (i.e., increase of elastic compliance) is a necessary condition for enhanced piezoelectric properties. Properties can be further maximized where a high spontaneous/remanent polarization can be retained. Despite four different phases coexist at the convergence point and the elastic compliance is comparable to that of the O/T phase boundary, a maximum in d_{33} is not observed at this composition, mainly due to the lower spontaneous/remanent polarization values determined by the small unit cell distortion.

The properties of BCTZ ceramics are highly dependent on processing, relative density, microstructure and poling conditions (Wang *et al.*, 2011; Bai *et al.*, 2015; Wu *et al.*, 2012; Praveen *et al.*, 2015; Hao *et al.*, 2012). In the case of powders prepared by solid-state reaction, factors like the precursor powder size and the calcination temperature can have a significant impact on the chemical homogeneity at local level. Differently from undoped BaTiO₃, which shows optimal values of properties in ceramics with grain size of ≈ 1 μm , the electro-mechanical constants d_{33}^* and d_{33} are maximized for a grain size of the order of 10–30 μm (Wang *et al.*, 2011; Bai *et al.*, 2015; Wu *et al.*, 2012; Praveen *et al.*, 2015; Hao *et al.*, 2012). Field cooling poling was found quite effective to improve the piezoelectric properties of BCTZ ceramics. This was attributed to the development of an internal bias field caused by the alignment of defect charge carriers, rather than higher degree of domain texture (Li *et al.*, 2013). A drawback of the BCTZ system is the relatively low T_C (70–75 °C for $x = 0.40$ and 90–95 °C for $x = 0.60$) which reduces the operating temperature range of the material. Furthermore, d_{33} decays rapidly with increasing temperature. The Curie point can be increased but at the expenses of the piezoelectric properties; for example $T_C = 114$ °C and $d_{33} = 450$ pC N⁻¹ in $(1-x)\text{Ba}(\text{Zr}_{0.15}\text{Ti}_{0.85})\text{O}_{3-x}(\text{Ba}_{0.8}\text{Ca}_{0.2})\text{TiO}_3$ for $x = 0.53$ (Bao *et al.*, 2010). Texturing is a common strategy to further enhancing the piezoelectric activity of ceramics by orienting the grains along a common and favorable crystallographic direction, using template grain growth. For [001] grain-oriented $(\text{Ba}_{0.94}\text{Ca}_{0.06})(\text{Ti}_{0.95}\text{Zr}_{0.05})\text{O}_3$ ceramics, a very high d_{33} of 755 pC N⁻¹ and an extremely large d_{33}^* coefficient of 2027 pm V⁻¹, along with a low strain hysteresis, were reported by Liu *et al.* (2017a).

Fig. 18 Map of piezoelectric coefficient d_{33} as a function of temperature and composition in the system $(1-x)\text{Ba}(\text{Ti}_{0.89}\text{Sn}_{0.11})\text{O}_{3-x}(\text{Ba}_{0.70}\text{Ca}_{0.30})\text{TiO}_3$. Reprinted with permission from ref. Zhao, C., Wu, H., Li, F., *et al.*, 2018. Practical high piezoelectricity in barium titanate ceramics utilizing multiphase convergence with broad structural flexibility. *Journal of the American Chemical Society* 140, 15252–15260. Copyright (2018) American Chemical Society.

The family of $(\text{Ba,Ca})(\text{Ti,Sn})\text{O}_3$ (BCTS) ceramics has also been investigated in detail and shows excellent piezoelectric properties, whereas the $(\text{Ba,Ca})(\text{Ti,Hf})\text{O}_3$ (BCTH) system was less extensively explored. The phase diagrams and the general features of BCTIZ, BCTS and BCTH systems are similar (Acosta *et al.*, 2017; Keeble *et al.*, 2013; Wang *et al.*, 2014; Zhu *et al.*, 2013a,b, 2014, 2016). Low signal $d_{33} > 500 \text{ pC N}^{-1}$ and $d_{33}^* > 1000 \text{ pm V}^{-1}$ were reported for a wide range of BCTS compositions in proximity of the O/T transition and, more generally, at the polymorphic phase transitions (Zhu *et al.*, 2013a,b, 2014, 2016; Janbua *et al.*, 2017). In particular, $d_{33} = 670 \text{ pC N}^{-1}$ for $x = 0.07\text{--}0.09$ and $d_{33}^* = 1414 \text{ pm V}^{-1}$ for $x = 0.11$ were reported in $\text{Ba}_{0.95}\text{Ca}_{0.05}\text{Ti}_{1-x}\text{Sn}_x\text{O}_3$ ceramics (Zhu *et al.*, 2013b). A remarkable piezoelectric coefficient, $d_{33} = 697 \text{ pC N}^{-1}$, was also measured in $\text{BaSn}_x\text{Ti}_{1-x}\text{O}_3$ ceramics with composition corresponding to the phase convergence point, $x = 0.11$, with T_C of 40°C (Yao *et al.*, 2012b). However, this material has limited interest, because of the inherent thermal instability and the incorporation of Ca is essential to stabilize the tetragonal phase at higher temperature. Very recently a detailed mapping of d_{33} (Fig. 18) has revealed values higher than 600 pC N^{-1} for a large range of compositions ($x = 0.06\text{--}0.23$) in $(1-x)\text{Ba}(\text{Ti}_{0.89}\text{Sn}_{0.11})\text{O}_{3-x}(\text{Ba}_{0.70}\text{Ca}_{0.30})\text{TiO}_3$ ceramics at room temperature, with a maximum of 700 pC N^{-1} for $x = 0.18$ (Zhao *et al.*, 2018). Despite the high piezoelectric activity, the T_C of the compositions with the best properties is only $60\text{--}70^\circ\text{C}$ and, consequently, a rapid drop of d_{33} is observed with increasing temperature. BCTH ceramics generally show a reduced piezoelectric activity in comparison to BCTIZ and BCTS (Wang *et al.*, 2014; Zhao *et al.*, 2016), with higher values of d_{33} at the R/O and O/T phase boundary, up to $\approx 500 \text{ pC N}^{-1}$ in $\text{Ba}_{0.85}\text{Ca}_{0.15}\text{Hf}_{0.1}\text{Ti}_{0.9}\text{O}_3$ with a Curie temperature of $\approx 85^\circ\text{C}$.

An improvement of the piezoelectric properties of BaTiO_3 can be obtained by adding a small amount of LiF, which also lowers the sintering temperature to 1100°C , i.e. at least $200\text{--}300^\circ\text{C}$ below the temperature generally employed. Li compounds such as Li_2O , Li_2CO_3 and LiF are well-known sintering aids, which promote densification by formation of a liquid phase and growth of grains with core-shell microstructure (Randall *et al.*, 1993). Yang *et al.* (2012) showed that the addition of 4 mol% LiF leads to $d_{33} = 270 \text{ pC N}^{-1}$ and $k_p = 0.45$, though T_C is lowered to 73°C . Kimura *et al.* (2013) sintered Li-doped ceramics with improved $d_{33} = 260 \text{ pC N}^{-1}$, $k_p = 0.44$ and $T_C = 130^\circ\text{C}$ using hydrothermally-synthesized powders. In both cases, the presence of Li stabilizes the orthorhombic phase at room temperature and this can contribute to the enhancement of the piezoelectric activity. Even higher d_{33} values $> 300 \text{ pC N}^{-1}$ were measured on undoped BaTiO_3 ceramics with grain size of $\approx 50 \mu\text{m}$ sintered at $1160\text{--}1230^\circ\text{C}$ from hydrothermal powders. The poled ceramics exhibited orthorhombic or mixed tetragonal-orthorhombic structure. Optimal properties, $d_{33} = 355 \text{ pC N}^{-1}$ and $k_p = 0.40$, were obtained after sintering at 1190°C (Ma *et al.*, 2012). Coarse-grained (grain size $> 10 \mu\text{m}$) ceramics densified by spark plasma sintering featured d_{33} values up to 416 pC N^{-1} (Shen and Li, 2010). In both cases, the enhancement of piezoelectric activity was ascribed to the presence of nanodomains with thickness of few tens of nanometers. However, the origin of these nanodomains is still unclear. As discussed in the next section, maximum piezoelectric activity is usually observed in ceramics with grains size around $1 \mu\text{m}$.

Size and Scaling Effects

The properties of ferroelectric materials, including BaTiO_3 , in form of films, particles and ceramics show a significant variation with decreasing the physical dimension (thickness for films, diameter for particles and grain size for ceramics) (Shaw *et al.*, 2000; Ihlefled *et al.*, 2016). Representative examples are provided by the dielectric response and the piezoelectric activity.

Kinoshita and Yamaji (1976) first reported a progressive increase of the dielectric permittivity of BaTiO_3 ceramics with decreasing the grain size from 53 to $1.1 \mu\text{m}$. A systematic lowering of saturation polarization, piezoelectric coefficients and electromechanical coupling constants with diminishing grain size ($4\text{--}0.2 \mu\text{m}$) was described in PZT ceramics by Randall *et al.* (1998). The room

Fig. 19 Room temperature dielectric constant of BaTiO₃ ceramics as a function of grain size. Data collected from different authors. HPS, hot pressing sintering; MAP, multi-anvil press; CSM, combined sintering method; SPS, spark plasma sintering; 2SS, two-step sintering.

temperature dielectric constant of barium titanate ceramics as a function of grain size, as obtained by plotting the data reported by several authors (Arlt *et al.*, 1985; Frey *et al.*, 1998; Takeuchi *et al.*, 2002; Polotai *et al.*, 2003; Zhao *et al.*, 2004; Wang *et al.*, 2006; Buscaglia *et al.*, 2006b; Deng *et al.*, 2006; Zhu *et al.*, 2008; Huan *et al.*, 2013), is shown in Fig. 19. A pronounced maximum with $\epsilon_r = 5000$ – 6000 is observed at a grain size of $\approx 1 \mu\text{m}$. These values are 3–4 times higher than the dielectric permittivity (≈ 1500) measured in ceramics with grain size $> 10 \mu\text{m}$. The permittivity is significantly suppressed to values even lower than 1000 in ceramics with nanosized grains.

The piezoelectric coefficient d_{33} exhibits a trend similar to dielectric permittivity, with a maximum $> 500 \text{ pC N}^{-1}$ again at $\approx 1 \mu\text{m}$ (Shao *et al.*, 2008; Zheng *et al.*, 2012; Huan *et al.*, 2014; Tan *et al.*, 2015; Hoshina *et al.*, 2018) to be compared with the piezoelectric coefficient of coarse grained ceramics, 180 – 190 pC N^{-1} (Fig. 20). However, some data sets indicate the existence of a broad maximum at a grain size of 4 – $5 \mu\text{m}$.

Size and scaling effects in ferroelectric materials have received significant attention for over five decades. Besides the fundamental question of determining the critical size at which ferroelectric order vanishes, many studies have been driven by the continuous miniaturization process of virtually all active and passive electronic components, with a size reduction of the functional material inside the devices. Ferroelectric perovskites are used in different devices, including MLCCs, non-volatile memories (FERAMs) and multilayer piezoelectric transducers and actuators. A typical example of device downsizing is represented by MLCCs, widely used in consumer electronics, smartphones, hybrid and electrical vehicles. A typical multilayer capacitor is essentially a parallel connection of many stacked ceramic plate capacitors (Kishi *et al.*, 2003; Pan and Randall, 2010). The interdigitated conducting layers form the counter-electrodes for each dielectric layer. The capacitance of a MLCC is given by

$$C = \epsilon_0 \epsilon' n \frac{S}{t}$$

where S is the overlap electrode area, t the thickness of the single dielectric layer, n the number of layers and ϵ_0 the permittivity of vacuum. A reduction of the case size keeping the capacitance constant can then be obtained by decreasing the geometric parameters t and S or the lateral size of the capacitor if n is increased.

In the last 20 years the typical thickness of the dielectric layers has decreased from 10 to $0.5 \mu\text{m}$. Most of the capacitors are fabricated using the nickel inner electrodes technology, that co-fires the BaTiO₃ based dielectrics with Ni-electrode layers in a reducing atmosphere (Kishi *et al.*, 2003; Pan and Randall, 2010). Taking into account that, for reasons of long-term reliability, it is preferable to have several grains (5 – 7) spanning the thickness of each dielectric layer, the grain size of top edge MLCCs is of the order of 100 nm or even less. The dielectric constant of BaTiO₃ is significantly suppressed (< 2000) when the grain size approaches the nanoscale region and this trend continues with further reducing the grain size (Fig. 19), with a significant effect on the capacitor performance. In fact, the same depression reported for undoped ceramics is also exhibited by BaTiO₃-based dielectrics used in XNR ($N = 6$ – 9) capacitors. For example, the dielectric constant of X7R compliant ceramics decreases from ≈ 2800 to ≈ 2000 while decreasing the grain size from 460 to 120 nm (Gong *et al.*, 2014).

The scaling of properties is mainly of extrinsic origin and determined by the contribution of different types of interfaces such as grain boundaries, domain walls and other extended defects, whose concentration or volume fraction changes as the system size scales (Shaw *et al.*, 2000; Ihlefeld *et al.*, 2016). A detailed discussion of the mechanisms responsible for size and scaling effects in ferroelectrics is beyond the aim of this contribution and only some general results are summarized below. Recent reviews can be found in Ihlefeld *et al.* (2016) and Buscaglia and Randall (2020).

Fig. 20 Room temperature piezoelectric coefficient d_{33} of BaTiO₃ ceramics as a function of grain size. Data collected from different authors.

The domain configuration, the domain wall density and the domain wall mobility change with the grain size and this determines a dimension-dependent contribution to permittivity and piezoelectric properties. As anticipated in Section “Crystal Structure, Nonstoichiometry and Defect Chemistry of BaTiO₃”, the domain wall movement represents the major extrinsic contribution to the dielectric and piezoelectric properties at low and moderate fields (Damjanovic, 1998).

The domain configuration becomes simpler with decreasing grain size (Fig. 21). Coarse grained ceramics ($> \approx 10 \mu\text{m}$) show complex three-dimensional arrangements of 90° and 180° domain walls and their dielectric permittivity is practically constant. Below $5\text{--}7 \mu\text{m}$, the grains predominantly exhibit stripe domain patterns with domains separated by 90° walls. The domain width decreases from 0.3 to $0.4 \mu\text{m}$ to less than 100 nm in submicron ceramics. Domain walls are no longer observed when the grain size is smaller than $200\text{--}300 \text{ nm}$, and the grains mainly comprise single domains (Frey et al., 1998; Zhao et al., 2004; Buscaglia et al., 2006b; Arlt, 1990; Frey and Payne, 1996).

According to the model of Arlt et al. (1985), the permittivity of BaTiO₃ ceramics is given as the sum of two terms: the lattice contribution (assumed independent of grain size) and the domain wall contribution. When the grain size g is in the range $1\text{--}10 \mu\text{m}$, the width of the 90° domains is proportional to g^m with $m = \frac{1}{2}$ and, consequently, the dielectric permittivity increases with decreasing grain size with a $g^{-1/2}$ dependence, in agreement with the experimental data. The proportionality between the domain width and the square root of a characteristic length of the material (thickness for slabs, diameter for wires, lateral side for nanocubes) is a general property of ferroic crystals (Schilling et al., 2006, 2009) which was initially proposed by Kittel for ferromagnetic materials. When $g < 1 \mu\text{m}$, m rises to values > 1 .

In the model, the wall mobility was assumed to be independent of grain size. Later, Arlt and Pertsev (1991) predicted that the domain wall mobility is also a function of the grain size. A recent investigation using in-situ synchrotron X-ray diffraction experiments on ceramics with different grain size ($0.3\text{--}3.5 \mu\text{m}$) has provided further insight into the dependence of mobility on grain size (Ghosh et al., 2014). It was shown that the motion of 90° domain walls is greatest under both strong (above coercive) and weak (below coercive) electric fields for an intermediate grain size of $\approx 2 \mu\text{m}$. Furthermore, the domain wall motion was strongly suppressed in the ceramic with grain size of $0.3 \mu\text{m}$. The reduction of wall mobility in ferroelectric ceramics with submicron and nanometric grains is also indicated by the progressive tilting of the P(E) hysteresis loops with a reduction of both remanent and saturation polarization (Frey et al., 1998; Buscaglia et al., 2006b; Curecheriu et al., 2012). Domain reorientation and switching become increasingly more difficult as the grain size is reduced towards the single domain grain regime.

There is general consensus that the grain boundaries in BaTiO₃ and other perovskites have a non-ferroelectric character and a much lower permittivity ($\epsilon' \approx 10^2$) than the grain cores ($\epsilon' \approx 10^3$) forming a “dead-layer” region which exerts an increasing dilution effect on the dielectric properties of ceramics with decreasing grain size, especially at submicron and nanometric scale (Frey et al., 1998; Zhao et al., 2004; Buscaglia et al., 2006b; Emelyanov et al., 2002; Curecheriu et al., 2010; Padurariu et al., 2012). The low permittivity grain boundaries determine a redistribution of the electric field inside the ceramic. Finite element modeling has shown that the effective electric field is higher than the applied field in the grain boundaries perpendicular to the direction of the applied field and lower in the grain cores. This inhomogeneity increases with decreasing grain size. A main effect of electric field redistribution is the progressive decrease of the nonlinear contribution to effective permittivity and of tunability (Padurariu et al., 2012) as the grain size goes down. The effect of grain boundaries has also been investigated by phase-field simulation based on Ginzburg-Landau kinetic equation with the grain size varying from 10 to 170 nm (Su et al., 2017). At low field the monotonic decrease of dielectric permittivity with decreasing grain size is confirmed. At high field, the dielectric and piezoelectric responses are dominated by the dynamics of domain structure above the grain size of 50 nm and by the properties of the dead layer below this value. As a result, the large field permittivity and d_{33} first increase and then decrease with a maximum at $\approx 50 \text{ nm}$. The distribution of polarization in the remnant state after field removal undergoes a profound alteration with decreasing grain size, from a

Fig. 21 SEM images of domain patterns observed in the various poled BaTiO₃ ceramics with different average grain size. (a) 0.74 μm . (b) 1.63 μm . (c) 3.95 μm . (d) 8.37 μm . A progressive evolution from simple stripe patterns to more complex domain arrangements is observed with increasing grain size. Reprinted from ref. Zheng, P., Zhang, J.L., Tan, Y.Q., Wang, C.L., 2012. Grain-size effects on dielectric and piezoelectric properties of poled BaTiO₃ ceramics. *Acta Materialia* 60, 5022–5030, with permission from Elsevier. Copyright Acta Materialia Inc. (2012).

monodomain state at 110 nm to a vortex organization at 15 nm. The change of polarization distribution is determined by the significant depolarization field associated to the “dead-layer”. A similar transition in the polarization was also predicted by [Fu and Bellaiche \(2003\)](#) in BaTiO₃ nanoparticles using a first-principles-based approach. Further experimental studies are needed to confirm these trends.

The enhancement of the dielectric strength with decreasing grains size experimentally observed ([Curecheriu et al., 2010](#)) has been elucidated by phase field modeling and ascribed to the higher breakdown energy of the grain boundaries with respect to grain cores ([Cai et al., 2018](#)). The impact of grain boundaries is also dependent on the Ba/Ti ratio. Ti-rich stoichiometries beyond the solubility limit cause the segregation of a crystalline or amorphous titania-rich layer which further amplifies the dilution effect. A significant binary oxide excess leads to the formation of secondary phase inclusions such as Ba₂TiO₄ (Ba-excess), BaTi₂O₅ and Ba₆Ti₁₇O₄₀ (Ti-excess) ([Lee et al., 2007a, 2001](#)).

Although the domain wall mobility probably plays a main role in determining the existence of the permittivity maximum in [Fig. 19](#), the dilution effect of grain boundaries gives an increasing and significant contribution to permittivity depression when the grain size is $< \approx 0.5 \mu\text{m}$ ([Frey et al., 1998](#); [Zhao et al., 2004](#)). Furthermore, the inhomogeneous distribution of the electric field in fine grained ceramics results in a decrease of the effective field in the grain core ([Padurariu et al., 2012](#)) with a negative impact on domain reorientation and switching ([Curecheriu et al., 2012](#)).

A broad dispersion of experimental data is apparent from [Figs. 19](#) and [20](#). The dispersion can be attributed to the use of powders synthesized with various methods and different precursors as well as to differences in subsequent processing, including sintering technique, sintering thermal parameters and possible post-sintering annealing treatment. The synthesis step introduces impurities of variable nature and amount as well as variability of the Ba/Ti ratio which, in turn, affects the lattice defects concentration and impacts all the properties. For example, coarse-grained ceramics sintered in the same conditions exhibited a room temperature dielectric constant in the range 950–1800, increasing the Ba/Ti molar ratio from 0.97 to 1.03 with maximum permittivity at 1.01 ([Lee et al., 2001](#)). The impact of stoichiometry can partly explain the broad dispersion of the piezoelectric

activity data, which is even larger than that of the permittivity response. Dai *et al.* (2018) systematically investigated the dependence of d_{33} on grain size for different values of the Ba/Ti ratio from 0.998 to 1.002. The maximum of d_{33} was found at a grain size of $\approx 1 \mu\text{m}$ when Ba/Ti ≥ 1 and at $\approx 4 \mu\text{m}$ when Ba/Ti < 1 , and this might justify the existence of two sets of data with a different trend in Fig. 20. Maximum piezoelectric activity ($> 500 \text{ pC/N}$) is attained at Ba/Ti = 1.

When the particle/grain size is reduced below $\approx 100 \text{ nm}$, the high fraction of surface/interface atoms produces a disturbance of the polar order, reducing the thermodynamic stability of the polar phase in comparison to the paraelectric modification, with a progressive decrease of T_C and spontaneous polarization until ferroelectricity will vanish below a critical size (Ihlefeld *et al.*, 2016; Zhong *et al.*, 1994). This phenomenon is usually referred to as “intrinsic” size effect and, along with the reduced domain wall mobility and the dilution effect of grain boundaries, will contribute to the downscaling of properties. The critical size for ferroelectricity is of the order of $\approx 10 \text{ nm}$ for isolated particles and grains in ceramics containing a low concentration of impurities and defects (Wang *et al.*, 2006; Ishikawa *et al.*, 1988; McCauley *et al.*, 1998; Polking *et al.*, 2012).

From the above discussion it is clear that multiple mechanisms combine to produce the maximization of the dielectric constant and piezoelectric properties exhibited by BaTiO₃ ceramics for an intermediate grain size and, more generally, the observed variations of properties with grain size. The size and scaling effects are further convoluted with spurious contributions related to stoichiometry, impurities and defects leading to a large dispersion of experimental data and the behavior of specific samples can be hardly understood without a comprehensive chemical and microstructural analysis.

The decline of permittivity and all other functional properties with decreasing grain size, albeit unavoidable, can be alleviated by the use of high purity precursors, a tight control of the Ba/Ti ratio and a careful processing. The coherence length and ferroelectric order will be enhanced in materials with high crystalline order, low defect concentration, absence of local strain gradients and internal stresses. A low level of impurities and a stoichiometry within the homogeneity range of the compound will decrease the effective thickness of the grain boundary layer and its dilution effect.

General Introduction

Piezoelectric and ferroelectric materials are present all around us and are an integral part of our lives, even though they may, at first glance, be invisible. In our cars, fuel consumption is optimized by piezoelectric injectors and safety is enhanced by airbags controlled by accelerometers. We use, store and transport our digital data thanks to non-volatile ferroelectric memories present in our solid state hard drives and our USB keys. We communicate with the help of smartphones equipped with touch screens and using microwave filters, allowing the transfer of data to relay antennas, which also make use of ferroelectric and piezoelectric materials.

Currently, lead-based compounds such as lead zirconate titanate (PZT) constitute the best family of piezoelectric and ferroelectric materials suitable for integration into devices such as piezoelectric actuators, sensors and transducers (Holterman and Groen, 2012). These compounds present excellent piezoelectric and ferroelectric properties and are widely industrially developed.

The development of these multiple and varied applications requires materials that can be modulated in properties. The most used solution to exacerbate these properties is the addition of dopant to the PZT composition. Different types of doping are possible depending on the desired piezoelectric characteristics. Complex and very diverse doped compositions depending on the targeted applications exist on the market.

Piezoelectricity: Definition and Application

Piezoelectric Phenomenon

The piezoelectricity describes the electrical polarization phenomenon induced by a mechanical deformation in some crystals. Thus, a piezoelectric material is a material with the ability to convert mechanical energy into electrical energy and vice versa (Craciun, 2020). The direct piezoelectric effect reflects the ability of a material to generate an electrical charge when it is subjected to mechanical stress. It is interesting to note that the electric charge is proportional to this stress. At the opposite, the reverse piezoelectric effect reflects the ability of a material to deform when an electric field is applied to it. Also in this case, the deformation is proportional to the applied field (Jaffe *et al.*, 1971; Moulson and Herbert, 2003). These phenomena are schematically represented in Fig. 1.

Among the 32 crystal classes, 11 have a center of symmetry and are nonpolar. For these, the application of a stress results in a symmetrical ionic displacement and, therefore, no change in the dipole moment. The other 21 classes are non-centrosymmetric, 20 are piezoelectric. Although class 432, of cubic symmetry, is non-centrosymmetric, it exhibits elements of symmetry which, combined, exclude the existence of polar features. Among the 20 piezoelectric crystal classes, 10 are polar, that is to say they have an electrical polarization in the absence of an applied external electric field. These 10 classes are called pyroelectric because the amplitude of the dipole moment depends of the temperature. Finally, a limited number of pyroelectric materials have the additional property of having a spontaneous polarization and the direction of this polarization can be reversed under the influence of an external electric field. This last group is called ferroelectric and the PZT family belongs to it. Classification and properties of crystal systems are shown in Fig. 2.

Piezoelectric devices are largely made from polycrystalline ferroelectric ceramics. After sintering, the spontaneous polarizations of the different domains are randomly oriented. At this time, the ceramic does not exhibit any macroscopic ferroelectric property. These materials can only be used for piezoelectric applications after having been subjected to an intense electric field which preferentially aligns the polarizations of the ferroelectric domains in its direction.

The mobility of these domains allows to explain the macroscopic polarization hysteresis cycles of these materials that are shown in Fig. 3.

When the electric field is removed, the polarized ceramic tends to return to its original form. The domains reorient themselves into their initial direction more or less quickly, revealing a hysteresis. The polarization P is then a nonlinear function of the external electric field E . For large electric field values, the polarization is saturated at the spontaneous polarization $\pm P_s$. When the electric field is reduced to zero, a remanent polarization $\pm P_r$ remains in the ceramic. If the electric field is equal to $\pm E_c$ then the remanent polarization is canceled. E_c is the coercive field.

Piezoelectric Applications

Two main materials have been developed for piezoelectric applications. The first ceramic developed was barium titanate (BaTiO_3) in the 1940s. The solid solution of lead zirconate titanate was discovered in the 1950s. Today, it is the most widely used for

piezoelectric applications because of its remarkable properties. Indeed, these materials have, compared to BaTiO₃, higher electromechanical coupling factor and Curie temperature allowing their use at higher temperature. Finally, due to the diversity of compositions existing in the PbZrO₃-PbTiO₃ system, PZT allows greater modulation of the properties and therefore of the applications.

These applications are very diverse due to the existence of direct and reverse effects (Moulson and Herbert, 2003). 4 major groups of applications of piezoelectric ceramics can be distinguished (Haertling, 1999):

- (1) Power generators: use of the direct effect from pressure constraints.
- (2) Pressure sensors and actuators: use of the indirect effect, slight movements are caused under the application of a field.
- (3) Generation of acoustic and ultrasonic vibrations: use of the indirect effect, the application of an alternating field generates vibrations.
- (4) Frequency control: the use of low impedance phenomenon at the resonant frequency of the material allows the selection of frequency bands.

More specifically, among the most famous applications, we find gas igniters, diesel engine injectors as well as airbag triggers using the direct piezoelectric effect but also actuators based on the reverse piezoelectric effect. Finally, mention may be made of the sensors used for reversing radar systems integrated into vehicles or echoscopy imaging systems, the operation of which is based on the two effects; direct and reverse (Holterman and Groen, 2012).

Piezoelectric Properties

Piezoelectric materials present several properties which are exploited depending the targeted applications. Their definitions are listed in this part.

Curie temperature T_c

The crystal structure of a material changes at the Curie temperature, T_c , from piezoelectric (non-centrosymmetric) to a non-piezoelectric (centrosymmetric) form. This phase change is accompanied by a peak in the dielectric constant and a complete loss of all piezoelectric properties.

Dielectric constant ϵ_r

The relative dielectric constant is defined as the ratio of the permittivity of the material ϵ^T to the permittivity of free space ϵ_0 . This is generally measured well below the mechanical resonance. The dielectric constant is derived from the static capacitance measurements at 1 kHz using a standard impedance bridge.

$$\epsilon_r = \frac{\epsilon^T}{\epsilon_0}$$

with: ϵ^T permittivity at constant stress (F/m) and ϵ_0 permittivity of free space (8.854×10^{-12} F/m).

Dielectric loss factor

The dielectric loss factor is defined as the tangent of the loss angle ($\tan \delta$). The loss factor represents the ratio of conductance to susceptance of a parallel equivalent circuit of the ceramic element. The loss factor can be measured directly using an impedance bridge.

Electromechanical coupling factor k

The electromechanical coupling factor of a piezoelectric material is a measure of the fraction of electric energy that can be converted into mechanical energy and vice versa:

$$k^2 = \frac{\text{mechanical energy converted into electric energy}}{\text{input mechanical energy}}$$

or

$$k^2 = \frac{\text{electric energy converted into mechanical energy}}{\text{input electric energy}}$$

The k_p is the electromechanical coupling factor in the radial mode (i.e., parallel to the surface of the material) and the k_t the electromechanical coupling factor in the thickness mode (i.e., perpendicular to the surface of the material).

Mechanical quality factor Q_m

The mechanical quality factor is the ratio of the reactance to the resistance in the series equivalent circuit representing the piezoelectric resonator. The Q_m factor is also related to the sharpness of the resonance frequency.

$$Q_m = \frac{f_a^2}{2\pi f_r Z_m C^T (f_a^2 - f_r^2)}$$

with: f_a anti-resonance frequency (Hz), f_r resonance frequency (Hz), Z_m minimum resonance at f_r (ohm) and C^T Capacitance of the material (F).

Alternatively, the Q_m factor can also be determined using the equation:

$$Q_m = \frac{f_r}{f_1 - f_2}$$

With: f_1 : -3 dB points from the resonance frequency f_r (Hz) and f_2 : $+3$ dB points from the resonance frequency f_r (Hz).

Piezoelectric constants d

The piezoelectric charge coefficient is the ratio of electric charge generated per unit area to an applied force (C/N or m/V).

$$d = \frac{\text{Strain developed}}{\text{Applied field}} = \frac{\text{Charge density}}{\text{Applied stress}}$$

In the d_{33} mode, the electrodes are perpendicular to the 3 axis and the applied stress or the piezoelectrically induced strain is in 3 direction.

Crystal Structure of $\text{Pb}(\text{Zr,Ti})\text{O}_3$

The lead zirconate titanate, $\text{Pb}(\text{Zr,Ti})\text{O}_3$ (PZT) is a solid solution composed of lead zirconate PbZrO_3 and lead titanate PbTiO_3 . This solid solution exists in all chemical composition domains of the PbTiO_3 - PbZrO_3 system. PbTiO_3 , PbZrO_3 and $\text{Pb}(\text{Zr,Ti})\text{O}_3$ belong to the family of perovskite-like ABX_3 compounds.

The perovskite structure flexibility allows a wide substitution variety according the choice of the atoms on A and B sites. In particular, the relation between the lengths of the A and B sub-networks plays an important role in the determination of the material properties. This relation is characterized by the Goldschmidt tolerance factor, t (Goldschmidt, 1926).

The Goldschmidt tolerance factor measures the deviation from the ideal situation of compact stacking of atoms and gives information on the stability of the perovskite structure as a function of the A, B and X ions radius.

$$t = \frac{r_A + r_X}{(r_B + r_X)\sqrt{2}}$$

Experimentally, the perovskite structure is stable for $0.88 < t < 1.10$. This allows a large variety of substitutions on A and B sites and, therefore, the existence of a large number of compounds having this structure.

The crystalline structure of the PZT is generally represented by a cubic lattice (Fig. 4). This structure is described as a cubic stacking of cations A, bivalent with a large radius and a coordination number of 12 (Pb^{2+}). The cation B, tetravalent with a smaller radius and a coordination number of 6 is positioned in the center of the lattice (Ti^{4+} or Zr^{4+}). The O^{2-} ions occupy the center of the cube faces (Jaffe *et al.*, 1971).

The chemical composition of the PZT is defined by the X and R parameters. X corresponds to the rate of Zr^{4+} ions occupying the B site of the perovskite network and is represented by the molar ratio:

$$X = \frac{n(\text{Zr})}{n(\text{Zr}) + n(\text{Ti})}$$

The second parameter, R, characterizes the occupation rate of the A sites compared to the B sites. It is represented by the molar ratio:

Fig. 4 Schematic representation of the perovskite structure. A2, A3 and A4 represent the deformation directions due to the displacement of the B ion into the octahedron.

Fig. 5 Bright-field (BF) TEM image showing 90° domains in 2.4 mol% Nb-doped PZT (Zr:Ti ratio: 1.095). Reproduced from: Zheng, H., Reaney, I.M., Lee, W.E., Jones, N., Thomas, H., 2001. Effects of strontium substitution in Nb-doped PZT ceramics. *Journal of the European Ceramic Society* 21, 1371–1375. doi:10.1016/S0955-2219(01)00021-8.

$$R = \frac{n(\text{Pb})}{n(\text{Zr}) + n(\text{Ti})}$$

Thus, the chemical formula of the PZT is written $\text{Pb}_R(\text{Zr}_x\text{Ti}_{1-x})\text{O}_3$.

The cubic structure for the PbTiO_3 , PbZrO_3 and $\text{Pb}(\text{Zr}_x\text{Ti}_{1-x})\text{O}_3$ species is stable only at high temperature. Under this form, the PZT material present a dielectric behavior characterized by a zero electrical polarization. This is the paraelectrical state. Below this temperature, named Curie Temperature (T_C), the crystal lattice is deformed spontaneously inducing the off-centering of the B cation within its octahedron. This phenomenon generates the apparition of an electrical dipole at the lattice scale and the formation of ferroelectric domains at the microscopic scale (Fig. 5). The phase diagram PbTiO_3 - PbZrO_3 was initially presented by Jaffe *et al.* (Fig. 6).

The lead titanate adopts a tetragonal structure below $T_C = 490^\circ\text{C}$ and presents a ferroelectric behavior. At the other end of the diagram, the lead zirconate presents an orthorhombic structure below $T_C = 230^\circ\text{C}$ and exhibits a antiferroelectric behavior. In the solid solution, the substitution of the Ti^{4+} ions by the Zr^{4+} ions induces a decrease of the Curie Temperature. Below this temperature, the crystal structure and the ferroelectric characteristics of the PZT evolve with its chemical composition.

Therefore, at room temperature, for zirconium rich compositions, the orthorhombic structure and antiferroelectric behavior of the PZT material exists only up to $x = 0.94$. Below this limit, PZT adopts ferroelectric behavior but has two different crystalline structures (Shirane *et al.*, 1952): for titanium rich composition, PZT crystallizes in the tetragonal system and for an intermediate PZT enriched in zirconium, the structure is rhombohedral. The remarkable fact of this PZT solid solution is the crystal system change for the composition around $x = 0.54$. It is admitted that at this place, there is a coexistence of the two rhombohedral and tetragonal phases for the same chemical composition. This transition is called morphotropic phase boundary.

The word “domain” reflects the experimental ambiguity in developing PZT ceramics with only one composition but fluctuating perfectly between two crystalline structures. In this ideal case, the system free energy is maximum (Budimir *et al.*, 2006). As both phases are piezoelectric, an exchange term appears and the resulting properties are then exacerbated.

Many authors have attempted to define as closely as possible this morphotropic transformation zone (Guarany *et al.*, 2007; Mabud, 1980; Noheda *et al.*, 2000a,b; Ragini *et al.*, 2002). However, it is really difficult to obtain a perfect chemical homogeneity in zirconium and titanium. The slightest heterogeneity results in the shifting of the zirconium enriched zone in the rhombohedral structure and conversely of the depleted zone in the tetragonal structure.

The interest of the morphotropic zone was highlighted by Jaffe *et al.* as part of the study of the piezoelectric properties according to the chemical composition x of the PZT (Jaffe *et al.*, 1971). It is in this area that maximum piezoelectric activity is observed. The dielectric constant, the electromechanical coupling factors and the piezoelectric constants present their optimal values around $x = 0.54$.

Following Jaffe’s work, it has been shown that for well synthesized morphotropic PZT compositions, the material exhibited another stable phase (Guarany *et al.*, 2007; Noheda *et al.*, 2000a). A slight monoclinic domain appears between the rhombohedral and tetragonal zones. This domain acts as a crystallographic intermediary between the two previous zones. The updated zone of the phase diagram is presented in Fig. 7.

Synthesis Routes

In most of the applications, PZT materials are used in the form of bulk polycrystalline ceramics. The elaboration of theses ceramics is based on two fundamentals stages: the powder synthesis and the material densification. The choice of the powder fabrication

Hyperfine interaction measurements on ceramics: PZT revisited *Physica B: Condensed Matter, Proceedings of the International Workshop "35th Anniversary of Hyperfine Interactions at La Plata" and "Humboldt Kolleg on Solid State Physics"* 389 2007 130 134. doi:[10.1016/j.physb.2006.07.039](https://doi.org/10.1016/j.physb.2006.07.039).

process is made on the basis of speed and simplicity of production and on the minimization of manufacturing costs. The most used current process is the solid state reaction of oxide precursors (Matsuo and Sasaki, 1965). Powders obtained with this synthesis route are usually sintered at temperatures around 1200°C. Other synthesis routes have been studied, especially to reduce the sintering temperature. Some examples are given from the following studies.

Texier *et al.* (2001) synthesized an Mn, Sb, W, Ni doped PZT by hydrothermal route. Dense and chemically homogeneous bulk ceramics were obtained at low temperature (950–1000°C) with comparable dielectric and piezoelectric properties ($k_p = 0.51$, $\epsilon_r = 1115$ and $d_{33} = 310$ pC/N) as for ceramics prepared by conventional way.

Nano-size powders of $Pb(Zr_{0.53}Ti_{0.47})O_3$ were fabricated by a milling coprecipitation method by Kim *et al.* (2004). Ceramics dense at 98% presenting high electromechanical coupling factor ($K_p = 0.58$) were obtained for a low sintering temperature of 900°C.

Sahoo *et al.* (2006) prepared $\text{Pb}(\text{Zr}_x\text{Ti}_{1-x})\text{O}_3$ ($0.48 \leq x \leq 0.54$) doped with La or Nd by wet chemical route using water soluble precursors. Sintering was performed at 1250°C and properties similar to undoped PZT were obtained for Lanthanum doped samples ($d_{33} = 273$ pC/N and $\epsilon_r = 1000$).

A sol gel auto-combustion method was used by Montanari *et al.* (2005) to synthesize highly homogeneous niobium doped PZT materials presenting nano-sized crystallites. Sintering was performed at 1100°C . Obtained piezoelectric constants were higher or comparable with those of samples obtained via traditional mixed oxide method.

Piezoelectric Properties of the PZT

At high temperature, PZT crystallizes in a cubic structure. A polarization cannot exist at this temperature. Approaching the Curie transition temperature, an elongation of the cubic lattice is observed. The symmetry then becomes rhombohedral (elongation along A3 axis) or tetragonal (elongation along A4 axis) (Fig. 4) and the PZT ceramics can be polarized.

The PZT Curie temperature varies from 230 up to 400°C depending on the composition (Wang *et al.*, 2015; Zhang *et al.*, 2005). Jaffe *et al.* (1971, 1954) showed that in the PbZrO_3 - PbTiO_3 phase diagram, some compositions present high piezoelectric properties. In particular, the dielectric constant and the electromechanical coupling factor reach their maximal values, respectively 750 and 0.40 for the morphotropic composition $\text{Pb}(\text{Zr}_{0.52}\text{Ti}_{0.48})\text{O}_3$. The mechanical quality factor has a maximum value of about 1200 for the composition $\text{Pb}(\text{Zr}_{0.48}\text{Ti}_{0.52})\text{O}_3$.

Piezoelectric properties of PZT ceramics can be modified by many factors:

- (1) The structure and the composition. The use of dopants can increase or decrease targeted properties.
- (2) External factors as mechanical strains (Algueró *et al.*, 2001), electric fields or temperature.
- (3) The lack of homogeneity and manufacturing reliability. Problems during ceramics manufacturing like lead volatilization or the appearance of parasitic secondary phases can change the properties of the ceramics (Eyraud *et al.*, 1981a; Guha *et al.*, 1988).
- (4) The aging and fatigue of the materials after polarization (Genenko *et al.*, 2015). Aging describes the gradual changes in material properties over time under external equilibrium conditions. Fatigue is characterized by a gradual change of the properties during service.
- (5) Porosity. Ferroelectric ceramics such as PZT with too low densities are hardly polarizable; most of the time, electrical breakdown occurs during the poling step leading to the destruction of the material (Jean *et al.*, 2018).

It is therefore important to control the ceramic process in order to obtain materials presenting optimized electrical properties.

PZT Properties Modification by Doping

Properties of lead titanate zirconate solid solutions can be modified by adding a small amount (1%–2% in mass) of elements called dopants. These ions substitute the Pb^{2+} ions (A site doping) or the Zr^{4+} and Ti^{4+} ions (B site doping). The valence of the dopant may be the same or different from that of the substituted ion. Different kinds of doping are possible (Jaffe *et al.*, 1971):

- (1) Isovalent substitutions: the dopant substitute ions with the same valence and almost the same size.
- (2) Substitutions with acceptor dopants: the dopant has a lower valence than the substituted ion.
- (3) Substitutions with donor dopants: the dopant has a higher valence than the substituted ion.
- (4) Substitutions with valence compensation: solid solutions are added in the system.
- (5) Multiple-valency additives: dopants with different valences but almost the same sizes are added in the system.

The dopants have different impact on the piezoelectric properties of the PZT ceramics. In this part, we will endeavor to present the bibliographic results as clearly as possible. Indeed, generally, only the intrinsic effect (structural) of the dopant is argued by the authors. In the absence of clear indications on the microstructure, extrinsic effects cannot be presented.

Most of time, studies on PZT doping are based on a “trial and error” strategy. One or more dopants are inserted into the material during the powder synthesis and/or before the sintering step and the properties are measured on the obtained ceramics. However, it is impossible to observe exactly if the dopant inserts itself in the structure, volatilize in some part or remains partially at grain boundaries. Furthermore, it is also complicated to dissociate the intrinsic effects of the dopant (insertion in the solid solution of PZT) from some extrinsic effect (i.e., modification of densification mechanisms and so on grain coarsening of the ceramic). Added to this is the impact of synthesis and sintering routes. For example, Courtois *et al.* (2006) showed that the addition of nickel had a positive impact on the mechanical quality factor during sintering of solid state synthesized powders, but a negative effect when the powder was hydrothermally synthesized.

Thus, a dopant can have an impact on the sintering, on the microstructure of the material and therefore on its properties. It can also have an intrinsic effect on the electrical properties of the PZT ceramic. All these contributions may affect final piezoelectric properties. It is then difficult for authors to clearly discriminate the different contributions of dopants for a better understanding of their effects on piezoelectric properties.

Isovalent doping

The most common isovalent substitutions are Sr^{2+} , Ca^{2+} and Ba^{2+} on the A site of the perovskite (Jaffe *et al.*, 1971). These ions have an important impact on the Curie Temperature (T_c decreases with the addition of strontium) and on the phases existence (enlargement of the quadratic phase with the addition of barium and strontium) leading to high piezoelectric properties (Kulcsar, 1959a).

Eyraud *et al.* (1981b) show important effects for addition of two dopants. Indeed, they report an increase of the electromechanical coupling factor k for a double isovalent substitution on the A site (12 at% Sr and 5 at% Ba) with conservation of the Goldschmidt factor and an increased atomic packing factor. They don't observe a noticeable decrease of the remnant polarization P_r and the mechanical quality factor Q . The improvement of the properties is attributed to the mobility of the ions on the A site.

This kind of doping is carried out in cases where relatively high piezoelectric properties are required around room temperature and no high temperature application is needed. This is typically done for materials which are used in actuator applications (Holterman and Groen, 2012).

Acceptor doping

In this case, doping is done with elements having lower valences than the substituted ions. This leads to the formation of oxygen vacancies for charge compensation and to the contraction of the crystal lattice (Jaffe *et al.*, 1971). Oxygen ions form a continuous network in the PZT cell and ions-vacancies displacement are facilitated. This acceptor-vacancy dipole is less stable than the donor-vacancy dipole. Once oriented, these dipoles will form a network stabilizing the domains structure (Moulson and Herbert, 2003). Due to the inhibition of the movements of the domain walls, dielectric constant ϵ and dielectric losses $\tan\delta$ decrease while mechanical quality factor Q_m and coercive field E_c increase. This leads to a slow-down of aging and to materials that are more difficult to polarize and depolarize. This is typical of so-called hard ceramics. The most used electron acceptor dopants are K^+ on the A site of the perovskite and Sc^{3+} , Mg^{2+} , Fe^{3+} , Co^{3+} and Cu^{2+} for the B site of the perovskite.

Moure *et al.* (1992) studied the influence of donor or acceptor dopants addition on a morphotropic PZT. More precisely, they focused on the addition of 1 at% of Fe^{3+} on the B site of the perovskite. The obtained material reaches a relative density of 98% after sintering at 1150°C for 2 h, despite a mass loss. Moure *et al.* (1992) attributed this mass loss to the evaporation of a part of the PbO. The microstructure is fine and homogeneous with a grain size around 1 μm and does not change with the increase of the sintering time. According to the authors, the control of the microstructure is due to oxygen vacancies formed as a consequence of the acceptor doping with iron. These vacancies limit the migration of the grains boundaries and thus, the grain growth. These ceramics present low dielectric losses (0.25%) and a high mechanical quality factor ($Q_m = 650$). According to Moure *et al.*, the improvement of the piezoelectric properties is linked to the diminution of the PbO present in the grain boundaries.

Fernandez *et al.* studied the impact of the iron addition on a niobium doped PZT (Fernández *et al.*, 1998). Various sintering conditions were tested with temperatures from 1070 to 1190°C and times from 1 to 8 h. The best properties were obtained for sintering at 1150°C during 2 h. According to the authors, at this temperature, the iron gets in the PZT network and plays its acceptor dopant role. Moreover, in this case, the material properties seem independent from the grains size. Indeed, the microstructure does not evolve neither with the temperature nor with the time but the electrical properties reach their highest values for sintering at 1150°C during 2 h.

Donor doping

The addition of donor dopants leads to the formation of cationic vacancies. Contrary to the oxygen vacancies, cationic vacancies present a scarce mobility. This can be explained by the anionic organization in the perovskite structure. The cations and cationic vacancies are separated by an oxygen ion which represents a considerable energetic barrier to cross to allow the cation-cationic vacancy exchange. Because of this low mobility, the donor-cationic vacancy dipole presents a stable orientation and its initial state is not affected by the spontaneous polarization or the applied field (Moulson and Herbert, 2003). Thus, this dipole does not participate in the electric response of the material.

On the other hand, this kind of doping causes a diminution of the concentration of oxygen vacancies. This leads to a decrease of the domain walls pinning phenomenon (Gerson, 1960). These domain walls will be more mobile inducing an increase of the dielectric constant ϵ and dielectric losses $\tan\delta$ and a decrease of the mechanical quality factor Q_m and the coercive field E_c . This leads to an acceleration of the aging and to materials easier to polarize and depolarize. This is typical of so-called soft ceramics (Jaffe *et al.*, 1971). The most used donor dopants are Bi^{3+} , La^{3+} and Nd^{3+} for the A site and Nb^{5+} , Sb^{5+} and W^{6+} for the B site of the perovskite.

Kulcsar works focused on dopants addition with +3 and +5 valences into PZT ceramics (Kulcsar, 1959b). He studied in particular doping with lanthanum and neodymium on A site and doping with niobium and thallium on B site of the perovskite. Kulcsar observed an increase of dielectric losses and electromechanical coupling factor but also an important increase of the dielectric constant with the addition of 1 wt% of lanthanum or neodymium. The author also observes a brutal decrease of the mechanical quality factor Q_m passing from 400 to 70. In the case of +5 valence addition, niobium has the same effect as lanthanum. In this case, optimal properties are obtained for an addition of 1 wt% of niobium. The combination of 0.5 wt% niobium and 0.5 wt% lanthanum provides material with the highest dielectric constant and electromechanical coupling factor.

Moure *et al.* studied the impact of a 4 at% Sb^{3+} doping on A site of a morphotropic PZT (Moure *et al.*, 1992). Mass losses are moderate and materials reach a relative density of 97%. The obtained materials present high electromechanical coupling factor and piezoelectric constant values ($k_p = 0.55$ and $d_{33} = 270 \text{ pC/N}$) but low mechanical quality factor ($Q_m = 100$).

Substitutions with valence compensation

The compounds used for the valence compensated substitution are of the perovskite type and form a solid solution with the PZT (Uchino, 2012). Several compounds have been studied such as $\text{Pb}(\text{Mg}_{1/3}\text{Nb}_{2/3})\text{O}_3$, $\text{Pb}(\text{Nb}_{1/2}\text{Fe}_{1/2})\text{O}_3$, $\text{Pb}(\text{Ni}_{1/3}\text{Nb}_{2/3})\text{O}_3$, $\text{Pb}(\text{Co}_{1/2}\text{W}_{1/2})\text{O}_3$, $\text{Pb}(\text{Mn}_{1/3}\text{Sb}_{2/3})\text{O}_3$, $\text{Pb}(\text{Mn}_{1/3}\text{Nb}_{2/3})\text{O}_3$, $\text{Pb}(\text{Sb}_{1/2}\text{Nb}_{1/2})\text{O}_3$, $\text{Pb}(\text{Mg}_{1/2}\text{W}_{1/2})\text{O}_3$, $\text{Pb}(\text{Y}_{2/3}\text{W}_{1/3})\text{O}_3$ or $\text{Ba}(\text{Cu}_{1/2}\text{W}_{1/2})\text{O}_3$ (Dong *et al.*, 1993; Moon and Jang, 1993; Murakami *et al.*, 1995; Tapaonoi *et al.*, 1994; Uchino, 2012; Yoon *et al.*, 1997) with different effects on PZT properties.

Several results have been observed with this kind of dopants. Each solid solution has its own effect on the material. Moreover, the doping with a solid solution does not only influence the electrical properties of the material but also the sintering conditions.

Doping with $\text{Pb}(\text{Ni}_{1/3}\text{Nb}_{2/3})\text{O}_3$ (Moon and Jang, 1993), $\text{Ba}(\text{Cu}_{1/2}\text{W}_{1/2})\text{O}_3$ and BiFeO_3 (Dong *et al.*, 1993; Murakami *et al.*, 1995) leads to a decrease of the sintering temperature. Hence, these compounds play the role of dopant in the PZT structure but also a role of sintering aid during a part or the totality of the densification cycle. This sintering aids can be found in two forms in the sintered materials: either they enter in substitution in the PZT network and play a role as dopant or they stay in the grain boundaries. In this second case, they generally form an amorphous non ferroelectric phase (Murakami *et al.*, 1995). This secondary phase has an impact on the electrical properties and most often a drop in properties is observed with the persistence of the secondary phase.

The doping by adding a solid solution into the PZT remains a complex method. The valence of the dopant has to be taken into account to favor soft or hard piezoelectric properties. Moreover, all the ceramic process has to be adapted to control the microstructure and avoid electrical properties degradation. However, the diversity of the possible composition is an advantage that allows for a broad scanning of applications based on the exacerbated properties. For example, Moon and Jang report an increase of the dielectric constant ϵ while the mechanical quality factor Q decreases for PZT doped with $\text{Pb}(\text{Ni}_{1/3}\text{Nb}_{2/3})\text{O}_3$ and sintered under oxidizing atmosphere (Moon and Jang, 1993). This corresponds to the behavior of hard PZT ceramic. Dong *et al.* (1993) on the other side, observed an improvement of the mechanical quality factor Q_m while the dielectric losses $\tan\delta$ decrease for a PZT doped with $\text{Ba}(\text{Cu}_{1/2}\text{W}_{1/2})\text{O}_3$ and BiFeO_3 . This is typical from soft PZT ceramics.

Multiple-valency additives

In this case, elements with multiple valence are used as dopants. These elements can play a role of donor or acceptor according to their oxidation state (Liang and Wu, 1993). The most used elements are the chromium and the manganese.

According to Jaffe *et al.* (1971) the insertion of chromium into the PZT structure causes an increase of the mechanical quality factor Q_m , a decrease of the electromechanical coupling factor and the aging of the material. The ionic radius of chromium suggests its insertion into the B site of the perovskite. According to its oxidation state, +3 or +6, it will have an acceptor or a donor effect respectively. Chromium doped PZT ceramics are widely used as filters due to their high mechanical quality factor Q_m and the stability of the resonance and antiresonance frequencies with temperature (Uchida and Ikeda, 1967).

The PZT doping with manganese has been widely studied (Banno and Tsunooka, 1967; Cheon and Lee, 1999; Hase *et al.*, 1993; Hennings and Pomplun, 1974; Park *et al.*, 1995; Peláiz Barranco *et al.*, 2001). This dopant is known to increase the electro-mechanical coupling factor. Manganese is too small to enter in the A-site of the perovskite and therefore it fits in the B-site. In their works, Henning and Pomplun show the presence of Mn^{2+} and Mn^{3+} ions on A-site for low PbO sintering atmosphere (Hennings and Pomplun, 1974). Hase *et al.* (1993) report that for a sintering temperature below 1100°C, the manganese contributes with PbO to the formation of a secondary phase at the grain boundaries. Above 1100°C, this secondary phase disappears and the manganese is supposed to enter the PZT network. For this temperature, they also notice a strong increase of the electromechanical coupling factor.

Manganese has also been studied simultaneously with other dopants. Banno and Tsunooka studied the effect of tungsten (Banno and Tsunooka, 1967). This element contributes to the formation of soft PZT ceramics (low mechanical quality factor and low coercive field). When a second dopant, MnO_2 , is added in the tungsten doped PZT, a strong increase of the mechanical quality factor and the coercive field is observed; the ceramics become hard. Furthermore, the tungsten manganese co-doped ceramics present poor aging of the piezoelectric properties and the dielectric constant is not affected.

The effect of manganese as co-dopant with niobium has also been studied by Park *et al.* (1995). The results are the same as those of Banno and Tsunooka with a transition from soft to hard ceramic behavior. PZT doped only with niobium exhibits the behavior of a soft ceramic. When manganese is added, the equivalent resistance for the resonance frequency decreases. This phenomenon is due to a decrease of the mechanical losses which impacts the piezoelectric properties and leads to an improvement in the mechanical quality factor.

In the same way, Peláiz Barranco *et al.* (2001) observed a modification of the properties of $\text{Pb}(\text{Zr}_{0.5}\text{Ti}_{0.44}(\text{Cu}_{0.25}\text{Nb}_{0.75})_{0.06})\text{O}_3$ when manganese is added. They attribute the strong increase of the mechanical quality factor to the manganese ion-oxygen vacancy dipole which pins the domain walls and induces a limitation of the vibrations and thus of mechanical losses.

Cheon and Lee, for their part, studied differences between doping with chromium, manganese and chromium-manganese co-doping of $(\text{Pb}_{0.9}\text{Sr}_{0.1})(\text{Zr}_{0.5}\text{Ti}_{0.5})\text{O}_3$ (PSZT) (Cheon and Lee, 1999). Doping of PSZT with chromium hardens the properties, the dielectric constant and the electromechanical coupling factor decrease while the mechanical quality factor increases. Doping of PSZT with manganese leads to a decrease of the grains size and improves the dielectric constant. Finally, the properties of the PSZT co-doped with chromium and manganese are intermediate: the piezoelectric properties are close to those of Cr-PSZT and the microstructure is those of the Mn-PSZT.

Microstructure – Properties Relations

The influence of dopants on electrical properties and microstructure has been widely studied. The microstructure-properties interaction is less reported. However, relationships between microstructure and electrical properties of PZT ceramics have been studied by some research teams. Most of time, literature deals with complex PZT compositions involving several dopants.

Webster and Weston's works focused on properties of various undoped PZT ($0.495 < x < 0.559$) (Webster and Weston, 1968). They studied several sintering profiles in order to vary the final microstructure of the ceramics. They observed that the dielectric constant and the dielectric losses values decrease with the increase of the grains size, with a stabilization for grain size of 5 μm . The piezoelectric properties increase with the grain growth. A step is observed again from 5 μm for the electro-mechanical coupling factor and the remnant polarization. On the other hand, the evolution of the electromechanical quality factor seems to be linked to the composition of the ceramic. Webster and Weston explain these evolutions by the different ferroelectric domains organizations with the different microstructures. Indeed, they highlighted by SEM observations, that in the larger-sized grains ceramics the domain size is of the same order of magnitude as the grain size in the finest-grained ceramics. So, the reorientation of the domains in the ceramics with fine microstructure is more difficult. This observation allows to explain the decrease of the polarization in fine-grained materials that leads to a decrease of the piezoelectric activity. According to Webster and Weston, the decrease of the dielectric constant with the increase of the grains size is linked to the formation of internal stresses in the material when passing the Curie temperature and the paraelectric-ferroelectric phase transformation. In the case of large grains, these stresses are relaxed by the formation of 90° ferroelectric domains but, for the fine-grained materials this relaxation is almost impossible. These internal stresses participate at the extrinsic part of the dielectric constant, which results in an increase of its value. The evolution of the dielectric losses is also due to these stresses. During the charge cycling, a stress/deformation hysteresis is added to the electric field/polarization hysteresis and contributes to the dielectric losses.

The ternary system $(1-x) \text{Pb}(\text{Zr}_{0.53}\text{Ti}_{0.47})\text{O}_3 - x \text{Pb}(\text{Sb}_{0.5}\text{Nb}_{0.5})\text{O}_3$ (PZT-PSN) was studied by Tapaonoi *et al.* (1994) for a substitution rate x included between 0 and 0.08. They observed that replacing PZT with PSN had no influence on the density of the ceramic pieces. On the other hand, they observed a strong decrease in grain size (5 μm to 1.9 μm) up to 3 mol% of PSN, then a stabilization of the grain size for greater substitution. The authors studied the effect of this microstructural change on the dielectric and piezoelectric properties of the ceramics. The Curie temperature and the electromechanical coupling factor k_p decrease with the PSN doping while the mechanical quality factor is improved. From these results, the authors defined an optimal composition containing 3 mol% of PSN. The grain size of the ceramics was then decreased up to 0.6–0.7 μm for this composition by grinding the powder. The study of the piezoelectric properties shows that the electromechanical coupling factor is not impacted by the decrease of the grain size. However, the piezoelectric constant d_{33} and the dielectric constant strongly decrease with the decrease of the grain size. The authors conclude that there is a grain size limit of 0.6 μm below which the decrease of the piezoelectric properties is catastrophic for the ceramics.

Randall *et al.* (1998) works focused on the evolution of the electrical properties of PZT ceramics and niobium doped PZT ceramics. Different sintering routes and conditions were applied in order to obtain grain sizes varying from 0.1 to 10 μm . The authors observed a decrease of the dielectric constant with the increase of the grains size. The remnant and maximum polarization increase with the grains size while the coercive field decrease. Randall *et al.* also observed the evolution of the lattice parameters in 0.4 mol% niobium doped PZT ceramics as a function of the grains size. The lattice distortion along the tetragonal c -axis is greatly reduced when the grain size is reduced to 1.0 μm , while the a -axis dimension is not as strongly affected. So, the crystal tetragonality, c/a , decreases as the grain size decreases. The authors attribute this result to an increase of internal stresses in materials showing a fine microstructure during the paraelectric-ferroelectric phase transition. The spontaneous unit-cell distortion is clamped in the fine-grained materials, which reduces the intrinsic polarization and also increases the internal stresses in the ceramic. The observation of the samples by transmission electron microscopy highlights the difference of configuration of ferroelectric domains with the grains size. In ceramics with grains size higher than 1 μm , different configuration of the domain in each grain exist. On the contrary, in the ceramics with submicrometer grain size, the domain configuration is unique: grains are simply striated, with the domains pinned to the grain boundary. This grain boundary/domains walls configuration complicates the domains reorientation and severely constrains the movement of domain walls. This result leads to the following consequences:

- (1) The reduction of the alignment of the ferroelectric domains leads to the reduction of the remanent polarization.
- (2) The decrease in the mobility of the domain walls leads to a reduction of the dielectric and piezoelectric coefficients.

These works are confirmed by a study of Arlt which particularly studied the influence of the microstructure on the organization of the ferroelectric domains and the properties of ferroelectric ceramics (Arlt, 1990). According to him, at the end of the sintering, during the temperature decrease, when passing the Curie temperature, each grain will deform spontaneously but will also be constrained by its neighbors. The grains deformation will be blocked and compensated by strong internal stresses. Compression stresses appear in the direction of expansion of the grains and tension stresses appear in the grains compaction direction. These internal stresses can be relaxed in the PZT by splitting the grains into ferroelectric domains. The size of these domains depends on the grain sizes according to the following relation:

$$d \sim \sqrt{g}$$

with d the domain size and g the grain size.

Arlt defines three domains arrangement modes in the ferroelectric ceramics according the grain size of the material. In case of coarse-grained ceramics, the arrangement of ferroelectric domains in a 3D network is possible. The internal stresses are insignificant. In fine-grained ceramics, the domains have a lamellar configuration and internal stresses are important. In very fine-grained ceramics (grain sizes of the same order of magnitude as the domains), the creation of domains is impossible due to too high internal stresses.

The properties of the material directly depend on its microstructural organization. Since the polarization is different on each side of the walls, the displacement of these walls under an electric field modifies the polarization. Therefore, the domain walls contribute to the different electrical properties of PZT ceramics. If the domain walls are pinned to the grain boundary or under stresses their displacement will decrease and thus, the material polarization and its properties will decrease too.

Conclusions on the Influence of Dopants and Microstructure on Electrical Properties of PZT

The electrical properties of ceramics are therefore sensitive to the chemical composition of the solid solution, to the temperature, but also to other factors. The substitutions or doping in the PZT lattice and the microstructure of the ceramic are thus essential factors.

The doping of PZT ceramics is complex. Theoretically, two main types of substitution exist and each have specific effects on the electrical properties of PZT ceramics. Donor doping generates dipoles formed by cationic vacancies and substituent ions. These dipoles have a stable orientation. They will not affect the mobility of the domain walls. The acceptor doping generates oxygen vacancies in the PZT lattice. Due to their mobility, the polarization of the "anionic vacancy-substituent ion" dipole can be changed under the influence of an external electric field. These dipoles, once oriented, will form a network stabilizing the structure of the domains resulting in the inhibition of the movements of the domain walls.

Thus, in the case of these dopants, it is the mobility of the domain walls which is the factor influencing the properties of PZT ceramics. When the mobility of the domain walls is facilitated, an increase of the dielectric constant and losses is observed while the mechanical quality factor and the coercive field are weak. The properties are reversed in the case of acceptor doping with pinned domain walls.

In reality, few of these simple mono dopants are used. The choice is rather on the use of codoping or addition of other solid solutions of perovskite structure which can form a solid solution with PZT. The preferential localization of these dopants in the PZT lattice or at the grain boundaries of the ceramic may cause a differentiation of the effects of these dopants leading to 3 possibilities. In the first case, the elements enter the PZT network and contribute to the electrical properties of the material. In the second case, the elements influence the ceramic sintering mechanisms and play the simple and unique role of sintering aids. In the third case, the integration of the dopants in the PZT lattice is partial. Thus, the dopants can be found in two forms in the sintered material. This can have a negative or a positive effect. In the case of a negative effect, the fraction of dopants remaining at the grain boundary contributes to the formation of non-ferroelectric secondary phases degrading the electrical properties of the ceramic. In the case of a positive effect, dopants can diffuse into the grains during sintering and then play the dual role of sintering aid and dopant leading to the non-precipitation of a secondary phase.

The use of solid solutions or co-doping is interesting but remains complex. It is not possible to define a precise effect of these doping. Valencies of dopants have to be taken into account in order to evaluate their influence on the electrical properties. The location of dopants is also an important factor. If they remain at the grain boundaries they will modify all the densification process, affecting the final microstructure and properties. Thus, all the ceramic process can be affected by the localization of dopants. Microstructural observations are therefore necessary for any possible conclusion on the role of each dopant.

The microstructure of a PZT ceramic is a factor controlling the domain structuring and the state of internal stresses when passing the Curie temperature. Thus, it greatly influences the dielectric and piezoelectric properties of the ceramic.

For ceramics with coarse microstructures, the organization of the domains into a 3D network is easy and domains are mobile. The stresses in the material are largely relaxed by a rearrangement of the ferroelectric domains. The polarization of the material is then facilitated and the piezoelectric activity increases. Thus, the piezoelectric properties are favored for coarse-grained ceramics. Internal stresses participate in the extrinsic part of the dielectric constant and in dielectric losses and for these coarse materials are less. It is also observed that in these coarse-grained ceramics dielectric losses and dielectric constant are low.

For ceramics with fine microstructures, the configuration of the ferroelectric domains becomes lamellar. Only 180° domains are present and the domain walls are pinned to the grain boundaries. It even seems that for a critical micron or submicron size, according to the authors, the creation of ferroelectric domains is impossible. The state of stress is high because the material could not relax them by an adequate domain structure. The polarization of the material is more difficult and the piezoelectric properties decrease. On the other hand, the contribution of the stresses to the dielectric properties being more important, the dielectric constant and the dielectric losses increase.

Conclusion

The lead zirconate titanate is therefore a material widely used in current technologies, both in the civilian field and in the military and medical fields. The main advantage of this material lies in the great modularity of its properties by the simple modification of

its composition. This particularity explains the extent of the field of application of this material. Regarding the industrial aspect, this material is widely exploited and the manufacturing processes are controlled. Regarding the aspect of research on this material, most of the phenomena have been interpreted, whether in terms of the dopants contribution or the relationships between the microstructure and the properties. Different synthesis and sintering routes have been investigated. Some questions remain about the exact nature of the morphotropic phase boundary. The situation would be idyllic if the PZT did not have the disadvantage of being largely composed of lead. As the toxicity of this element is no longer to be proven, research has been moving for the past twenty years towards alternative solutions free of lead. However, even though it is now accepted that PZT cannot be replaced by just one material, but by several depending on the targeted applications, none of the proposed candidates succeeded in achieving the performance level of PZTs. This material therefore remains the only one to be exploited at the industrial level in devices requiring piezoelectric components.

Introduction

Efforts to improve the environmental management of Waste of electrical and electronic equipment (WEEE), to contribute to a circular economy and to enhance resource efficiency, resulted in two directives issued by the European Commission. The WEEE Directive and the Restriction of Hazardous Substances Directive (RoHS1 (2003) and its revision, RoHS2 (2011)) aim at improving the collection, treatment and recovery of electronic components through recycling and reducing illegal export at their end-of-life. RoHS directive restricts the content of heavy metals, such as lead, mercury, and cadmium in electrical and electronic equipment and, more importantly, requires their substitution by safer alternatives. After the breakthrough 'Toyota' paper in 2004 revealed that Li-, Ta-, and Sb- modified sodium potassium niobate ceramics exhibit piezoelectric properties comparable to those of highly efficient and commercially most widespread lead-based piezoceramic $\text{Pb}(\text{Zr,Ti})\text{O}_3$ (PZT) and could replace it in applications (Saito *et al.*, 2004), expectations for lead-removal increased. The adopted regulations have prompted the replacement of lead in several applications, however, a number of exemptions exist, including PZT-based technologies for which adequate lead-free alternatives are not yet available. Nonetheless, the growing awareness of environmental and health issues related to the toxic emissions of PbO from PZT-based products by evaporation during processing or its release due to improper waste disposal, combined with the threat of removing current exemptions, has triggered widespread scientific interest in developing novel efficient lead-free alternatives. The environmental concerns and related regulation were recently reviewed by Bell and Deubzer (2018).

Three main groups of lead-free perovskite ferroelectric oxides have henceforth been considered as environment-friendly alternatives to PZT piezoceramics. These include sodium potassium niobate ($(\text{K,Na})\text{NbO}_3$)-based solid solutions, most commonly $(\text{K}_{0.5}\text{Na}_{0.5})\text{NbO}_3$ (KNN), sodium bismuth titanate ($\text{Na}_{1/2}\text{Bi}_{1/2}\text{TiO}_3$, NBT)-based piezoelectrics, and modified barium titanate (BaTiO_3 , BT), namely, barium calcium zirconate titanate ($(\text{Ba,Ca})(\text{Zr,Ti})\text{O}_3$, BCZT). While chemical modification of PZT, mainly donor or acceptor doping, results in a broad range of piezoelectric properties (Jaffe *et al.*, 1971), single lead-free material formulations do not exhibit the same property-diversity and cannot replace PZT. Even so, selected piezoelectric properties of individual lead-free materials are comparable to those of PZT and thus can be designed for specific applications (Rödel *et al.*, 2009, 2015; Koruza *et al.*, 2018a; Shibata *et al.*, 2018). For example, low density (KNN: 4.51 g cm^{-3} , about 55% of that of PZT) and good temperature stability make KNN-based materials good candidates for high-frequency imaging (Levassort *et al.*, 2011). Sodium bismuth titanate and related perovskite solid-solution derivatives, e.g., NBT-BT-KNN, show great potential for integration in applications where high electric-field-induced strain responses are required (Jo *et al.*, 2012; Liu and Tan, 2016; Tung *et al.*, 2019). BCZT has got exceptional piezoelectric properties suitable for actuation, however, these are obtained only within a narrow temperature window below its Curie temperature (below 100°C) (Liu and Ren, 2009). Another lead-free candidate of interest is the multiferroic and high-temperature piezoelectric BiFeO_3 or its modified formulations, such as BiFeO_3 -BT, however, it is not included in this review; please refer to Catalan and Scott (2009), Rojac *et al.* (2014, 2018), and Wang *et al.* (2018a).

Here, we briefly review the three main groups of lead-free perovskite piezoelectrics, KNN-, NBT-, and BT-based, we address the structure, phase relations, properties, synthesis and processing of these materials, link them to applications and discuss environmental and health concerns. We note that the topic of lead-free piezoceramics has been extensively covered in several reviews or books (Shrout and Zhang, 2007; Rödel *et al.*, 2009; Priya and Nahm, 2012; Coondoo *et al.*, 2013; Rödel *et al.*, 2015; Koruza *et al.*, 2018b; Rödel and Li, 2018; Wu, 2018).

Sodium Potassium Niobate

The discovery of ferroelectricity in NaNbO_3 and KNbO_3 dates back to 1949 (Matthias, 1949). Further investigations (Tennery and Hang, 1968; Jaffe *et al.*, 1971) showed that the ferroelectric orthorhombic KNbO_3 (*Amm*2) and antiferroelectric orthorhombic (*Pbma*) NaNbO_3 form a $(\text{K}_x\text{Na}_{1-x})\text{NbO}_3$ solid solution across the whole compositional range (Fig. 1(a)). The ferroelectric and piezoelectric properties peak in the proximity of the composition $(\text{K}_{0.5}\text{Na}_{0.5})\text{NbO}_3$, KNN (Egerton and Dillon, 1959). Early reports attributed this phenomenon to the formation of a morphotropic phase boundary (MPB) due to the coexistence of two orthorhombic phases at $x = 0.475$ (Tennery and Hang, 1968), and more recently at $x = 0.52$ (Dai *et al.*, 2009). The existence of the MPB has not been confirmed yet (Baker *et al.*, 2009; Tellier *et al.*, 2009).

The structure and phase transition sequence of pure KNN ceramics have been thoroughly investigated over the past decades (Shirane *et al.*, 1954; Tennery and Hang, 1968; Ahtee and Hewat, 1975; Tellier *et al.*, 2009). While a rhombohedral (*R3c*) polymorph (R) can be found at temperatures below -123°C , the crystallographic indexing of the room temperature phase is more complicated and thus often inconsistent in the literature as it depends on the selection of the appropriate unit cell, i.e., whether the initially proposed orthorhombic (*Amm*2) structure (O) with cell doubling or the perovskite type ABO_3 subcell with monoclinic (*Pm*) symmetry (M) are

used. The tetragonal ($P4mm$) phase (T) is present between 200°C and ~410°C (Curie temperature, T_C) and above the T_C , pure KNN retains the cubic ($Pm\bar{3}m$) phase (C) up to its solidus temperature at 1140°C (Fig. 1(a)). Early studies of the KNN ceramics reported a piezoelectric coefficient d_{33} of ~80 pC/N (Egerton and Dillon, 1959), while values of 110–160 pC/N were achieved later with the adjustment of the Na/K ratio and by improved processing (Fukada *et al.*, 2008; Lee *et al.*, 2008; Zhang *et al.*, 2007; Zuo *et al.*, 2006), including hot-pressing (Haertling, 1967; Jaeger and Egerton, 1962) and spark-plasma sintering (Bah *et al.*, 2014; Li *et al.*, 2006).

Strategies, such as phase-boundary engineering (Wang *et al.*, 2014; Zheng *et al.*, 2017; Wang *et al.*, 2009; Xing *et al.*, 2018; Zushi *et al.*, 2013; Karaki *et al.*, 2013; Wang *et al.*, 2015a; Zhang *et al.*, 2017a), domain engineering (Yao *et al.*, 2015; Zhao *et al.*, 2018) and

additional optimization of processing (Li *et al.*, 2006; Shen *et al.*, 2017), have been employed to improve its functional properties. Among these, chemical modification aiming at the construction of phase coexistence is the most frequently used approach (Zhang and Li, 2019). KNN has been modified by doping of A- (mostly with Li, Ag, Ca, Sr, and Ba) and/or B-sites (with Ta, Sb, Ti, Zr, Mn, and other elements), by formation of solid solutions with other ABO₃ perovskites (such as LiNbO₃, LiSbO₃, LiTaO₃, CaZrO₃, CaTiO₃, BaZrO₃, BaTiO₃, (Bi,K)HfO₃, etc.) and/or by addition of transition or post-transition metal oxides (CuO, ZnO, MnO, Mn₃O₄, MnO₂, Co₂O₃, Fe₂O₃, SnO₂), and sintering aids to the stoichiometric matrix in order to overcome inherent problems related to densification and sinterability (e.g., K₄CuNb₈O₂₃, K_{5.4}Cu_{1.3}Ta₁₀O₂₉) (Matsubara *et al.*, 2004, 2005; Ando, 2012; Coondoo *et al.*, 2013; Gupta *et al.*, 2012; Hao *et al.*, 2019; Li *et al.*, 2013a; Malič *et al.*, 2015; Rödel *et al.*, 2009; Safari and Hejazi, 2012; Ohbayashi *et al.*, 2017; Xing *et al.*, 2018; Wang *et al.*, 2018b; Wu, 2018; Zheng *et al.*, 2018). It is noteworthy that the underlying origin of the property enhancement in KNN-based solid solutions (Fig. 1(b)) is not a classical MPB, as in the case of PZT, but rather a polymorphic phase transition (PPT) effect (Dai *et al.*, 2007; Zhang *et al.*, 2006), resulting from downshifting of the O/M–T and/or upshifting of R–O/M phase-transition temperatures to room temperature due to the chemical modification. Particularly, the introduction of Sb⁵⁺ proved to be a highly efficient method for raising the R–O/M transition temperature and is often used to construct a distinct phase structure featuring a R–T phase transition at room temperature, which is commonly associated with enhanced piezoelectric properties. In this regard, Sb-modified KNN solid solutions have been known for their high electromechanical performance ever since the ‘Toyota’ paper (Saito *et al.*, 2004) and are currently dominating among KNN compositions by reaching d_{33} coefficients of 570 pC/N (Xu *et al.*, 2016) and in the case of textured ceramics even 700 pC/N (Li *et al.*, 2018). The drawbacks, however, remain in Sb toxicity and reproducibility of the functional properties in such multicomponent systems. Furthermore, the issue of thermal stability of properties due to temperature sensitivity of PPT has been recently addressed with new material concepts using phase-structure engineering, e.g., constructing a diffuse phase transition over a wide temperature range (Liu *et al.*, 2018; Wang *et al.*, 2013; Yao *et al.*, 2016; Zhang *et al.*, 2017b; Wang *et al.*, 2015a; Zhang *et al.*, 2017a).

Sodium Bismuth Titanate

Discovered in the 1960s (Smolenskii *et al.*, 1960), Na_{1/2}Bi_{1/2}TiO₃ (NBT) is a relaxor ferroelectric material showing frequency dispersion of its dielectric permittivity and a broad permittivity maximum at $T_m \approx 320^\circ\text{C}$. This feature is generally assigned to the dynamic fluctuations of nanometer-scaled polar regions (Petzelt *et al.*, 2004). NBT has a complex ABO₃ perovskite structure with mixed occupancy on the A site, with Na⁺ and Bi³⁺ differing in ionic radii and charge, causing strong random elastic and electric fields on the local lattice environment (Keeble *et al.*, 2013a). In addition, the Bi³⁺ ion has 6s² lone pair electrons that tend to hybridize with the 2p orbitals of oxygen, causing strong off-centering from its cuboctahedral site (Shuvaeva *et al.*, 2005).

Different polymorphs of the perovskite structure of NBT were identified, depending on temperature, pressure and electric field (Jones and Thomas, 2002; Kreisel *et al.*, 2003). At ambient conditions NBT was long considered as rhombohedral with long-range anti-phase tilting of the oxygen octahedra and cations displaced along the $\langle 111 \rangle$ directions (R3c), although still containing platelet-like remains of the high-temperature tetragonal phase with in-phase tilted octahedra and anti-parallel cation arrangement (P4bm) (Dorset and Trolliard, 2008; Levin and Reaney, 2012; Neagu and Tai, 2017). The structure was later defined as monoclinic (Cc) on the average scale (Gorfman and Thomas, 2010; Choe *et al.*, 2018). Furthermore, displacive disorder on the bismuth-site was shown to cause heterogeneous lattice distortions, strongly related to the coherence length of the oxygen octahedral tilting (Levin and Reaney, 2012; Aksel *et al.*, 2013; Usher *et al.*, 2015; Groszewicz *et al.*, 2016).

Despite strong polarization, high relative permittivity and low dielectric losses, NBT displays rather low figures of merit for piezoelectric applications compared to lead-based materials as it exhibits a rather small piezoelectric coefficient ($d_{33} \approx 73\text{--}95$ pC/N) and large coercive field ($E_c \approx 73$ kV/cm), a moderately high depolarization temperature ($T_d \approx 200^\circ\text{C}$), and strongly hysteretic charge- and strain-responses. In order to improve its electromechanical performances, NBT is engineered by designing MPB systems. Most commonly used counterpart members are BaTiO₃ (BT) (Takenaka *et al.*, 1991) and K_{0.5}Bi_{0.5}TiO₃ (KBT), (Elkechai *et al.*, 1996), both showing an average tetragonal symmetry. Despite the general view on MPB as the coexistence of tetragonal and rhombohedral structures, local probing revealed deviations from these average symmetries (Jiang *et al.*, 2017; Datta *et al.*, 2018; Levin *et al.*, 2019). The MPB in its virgin state is rather considered as an average pseudocubic structure with nanodomain texture (i.e., at/near 0.94NBT–0.06BT (Fig. 2(a)) and 0.80NBT–0.20KBT) (Ma *et al.*, 2010; Levin *et al.*, 2013; Otoničar *et al.*, 2017). Such a metastable state with a flattened free-energy potential can easily be influenced by external fields to reach multiple stable states. Furthermore, easy switching of nanodomains and strong domain texturing cause the MPB compositions to evolve with poling into a highly oriented polar state, exhibiting enhanced polarization and strain compared to the parent members (Daniels *et al.*, 2009; Hinterstein *et al.*, 2010; Jo *et al.*, 2011; Simons *et al.*, 2011; Craciun *et al.*, 2012; Ma *et al.*, 2012; Garg *et al.*, 2013; Schader *et al.*, 2016). The obtained highly coherent long-range symmetry state at higher applied fields was assigned to the increased interatomic correlations and phase transitions, strongly influenced by the loss of Bi–O covalency (Schütz *et al.*, 2012). While the field-induced long-range order in NBT–BT is remanent, adding KNN to the NBT–BT solid solution makes ordering reversible, contributing to large field-induced strains (Jo *et al.*, 2012). The enhanced electromechanical properties at the MPBs are thus related to the progressive decoupling of strain and polarization due to competing local distortions, which stem from chemical/charge disorder at the unit cell level, strong covalent bonding between cations and oxygen and field-induced reorientation/switching of nanoscale domains.

Vast variety of NBT-based systems with numerous dopants have so far been produced with the aim to increase d_{33} , strain response and/or depolarization temperature (Dinh *et al.*, 2015; Liu and Tan, 2016; Wu, 2018; Turki *et al.*, 2019). Further efforts for improving the

Fig. 2 (a) Partial phase diagram of the NBT–BT system in its virgin state, showing a broad morphotropic-phase region (*P4bm*) where tetragonal and/or rhombohedral long-range symmetries are induced with electric field or stress. (b) Evolution of dielectric permittivity (ϵ') and piezoelectric coefficient (d_{33}) with temperature in the poled 0.94NBT–0.06BT MPB composition; a sharp slope in permittivity curves at the temperature of depolarization coincides with a peak in d_{33} , above which the material is no longer piezoelectric. materials' functionalities have been undertaken through the role of defects (Spreitzer *et al.*, 2006; Yang *et al.*, 2018; Steiner *et al.*, 2019; Tung *et al.*, 2019) or ceramics texturing (Bai *et al.*, 2017), as well as on their integration into silicon technology (Tanaka *et al.*, 2018).

Barium Titanate

The discovery of ferroelectricity in barium titanate (BaTiO_3 , BT) at the beginning of the 2nd World War was stimulated by the need for high dielectric permittivity capacitors (Jaffe *et al.*, 1971; Haertling, 1999). Due to its excellent dielectric and ferroelectric properties, BT is still one of the most studied ferroelectrics. However, its modest piezoelectric properties, $k_p \approx 0.35$, $d_{33} \approx 190$ pC/N, and rather low T_C of 130°C (Jaffe *et al.*, 1971) could not compete with a much higher piezoelectric performance of PZT, which was discovered about 10 years later. Piezoelectric properties of BT-based materials were reviewed recently (Acosta *et al.*, 2017; Gao *et al.*, 2017, 2018).

Interest of the scientific community in piezoelectric performance of BT-based ceramics was revived in 2009 by the report on extremely high piezoelectric properties in calcium and zirconium modified BT ($(\text{Ba,Ca})(\text{Zr,Ti})\text{O}_3$, BCZT) ceramics (Liu and Ren, 2009). The respective quaternary solid solution, which had been originally studied as early as 1954 (McQuarrie and Behnke, 1954), could be treated as a quasi binary solid solution $(1-x)\text{Ba}(\text{Zr}_{0.2}\text{Ti}_{0.8})\text{O}_{3-x}(\text{Ba}_{0.7}\text{Ca}_{0.3})\text{TiO}_3$ (BZT– x BCT). The exceptional piezoelectric responses were reported for solid solutions in the vicinity of the optimized BZT–0.50BCT formulation with a peak d_{33} value of 620 pC/N, together with a high remanent polarization, low coercive field and high dielectric permittivity. Such high performance could not be explained by the proximity to T_C (93°C for BZT–0.50BCT), but was related to the phase boundary, i.e., MPB, between the rhombohedral BZT (R, $R3m$) and tetragonal BCT (T, $P4mm$) phases allowing many possible polarization states to coexist. At $x = 0.32$ composition of the BZT–BCT another point of phase coexistence was found at $T = 57^\circ\text{C}$, namely, between the R, T, and cubic (C, $Pm\bar{3}m$) phases, which was suggested to correspond to a tricritical point (Liu and Ren, 2009). Later studies revealed a mixture of R and T phases (Ehmke *et al.*, 2012; Haugen *et al.*, 2013), or a bridging orthorhombic phase (O, $Amm2$) between the R and T phases (Keeble *et al.*, 2013b; Acosta *et al.*, 2014). A pseudobinary BZT–BCT phase diagram and d_{33} coefficient as a function of composition and temperature are presented in Fig. 3. The phase relations and presence of a multiphase coexistence point (MCP) are topics of continued research (Keeble *et al.*, 2013a; Tian *et al.*, 2013; Zhang *et al.*, 2014; Heitmann and Rossetti, 2014; Acosta *et al.*, 2014, 2015a,b, 2017; Gao *et al.*, 2018). Transmission electron microscopy (TEM) revealed specific domain structures of individual phases of the BZT–BCT system. The off-MCP compositions, the BCT-rich T and BZT-rich R phases, were characterized by lamellar or wedge domains, respectively, while the MCP compositions, such as BZT–0.50BCT, showed nanodomains that were hierarchically arranged into larger, micron-sized domains. Furthermore, in-situ TEM studies revealed domains at the MCP to be highly susceptible to both temperature and electric field (Gao *et al.*, 2011, 2014; Guo *et al.*, 2014a; Lu *et al.*, 2014; Gao *et al.*, 2016a; Zakhozheva *et al.*, 2014, 2015), likely contributing to increased strain response. It was also found that the piezoelectric response of BZT–BCT strongly depends on the grain size (GS) (Ehmke *et al.*, 2012, 2013; Li *et al.*, 2013b; Bharathi and Varma, 2014; Guo *et al.*, 2014b; Tutuncu *et al.*, 2014; Zhang *et al.*, 2015; Bai *et al.*, 2016). In a systematic study of ceramics with GS from 0.4 to 32 μm , Hao *et al.* found that with increasing GS the phase transition temperatures decreased while the

Fig. 3 (a) Partial pseudobinary phase diagram of the BZT-BCT system. The dashed area marks the phase convergence region that could not be experimentally determined. (b) Dependence of the small signal d_{33} coefficient on the BZT-BCT composition and temperature. (a) Modified after Keeble, D.S., Benabdallah, F., Thomas, P.A., Maglione, M., Kreisel, J., 2013b. Revised structural phase diagram of $(\text{Ba}_{0.7}\text{Ca}_{0.3}\text{TiO}_3)$ - $(\text{BaZr}_{0.2}\text{Ti}_{0.8}\text{O}_3)$. *Applied Physics Letters* 102, 092903. (b) Reprinted from Acosta, M., Novak, N., Jo, W., Rödel, J., 2014. Relationship between electromechanical properties and phase diagram in the $\text{Ba}(\text{Zr}_{0.2}\text{Ti}_{0.8})\text{O}_{3-x}(\text{Ba}_{0.7}\text{Ca}_{0.3})\text{TiO}_3$ lead-free piezoceramic. *Acta Materialia* 80, 48–55, with permission of Elsevier.

physical properties (dielectric permittivity, remanent polarization, d_{33} , electromechanical coupling factors) increased, which was related to the influence of GS on the domain structure. The optimum properties were obtained for GS exceeding $10\ \mu\text{m}$ (Hao *et al.*, 2012).

Similar phase relations and high piezoelectric responses as in BZT-BCT were found in structurally analogous hafnium- and tin-substituted solid solutions (i.e., $(\text{Ba,Ca})(\text{Hf,Ti})\text{O}_3$ (Xue *et al.*, 2011); $(\text{Ba,Ca})(\text{Sn,Ti})\text{O}_3$ (Zhou *et al.*, 2012)). Doping of BZT-BCT with transition metals (e.g., Y, Cu, Zn, Cr, Mn) has been oriented towards reducing the high thermal budget and/or optimizing the functional properties (Han *et al.*, 2012; Li *et al.*, 2013c; Liu *et al.*, 2014a; Sun *et al.*, 2014; Wang *et al.*, 2015b; Chandrakala *et al.*, 2016; Xia *et al.*, 2016).

Processing

Bulk lead-free piezoelectric ceramics are most commonly prepared by solid-state synthesis, typically from metal oxide-carbonate mixtures, and sintering. In addition to conventional routes, alternative approaches have been introduced, such as solution routes and mechanochemical synthesis, or pressure-, electric field- or current-assisted sintering. The topic has been recently reviewed (Malič *et al.*, 2018; Wu, 2018).

Typical synthesis temperature ranges for KNN- and NBT-based formulations are between 700 and 900°C , for details on synthesis mechanisms refer to Malič *et al.* (2008), Aksel and Jones (2010), Kainz *et al.* (2014); Hou *et al.* (2017), and Koruza *et al.* (2016). KNN is notorious for humidity sensitivity of alkaline reagents, especially potassium carbonate, a narrow sintering range close to the solidus temperature (1140°C), difficult control of microstructure, easy appearance of secondary phases and chemical heterogeneity, especially in the case of chemical modification (Egerton and Dillon, 1959; Jaffe *et al.*, 1971; Malič *et al.*, 2015; Haugen *et al.*, 2015; Zhen and Li, 2006; Wang *et al.*, 2007; Acker *et al.*, 2010; Malič *et al.*, 2015; Radan *et al.*, 2018; Zhang and Li, 2019).

NBT requires sintering temperatures of about 1100°C to densify. Evaporation of bismuth, which contributes to coarsening of the microstructure, creation of oxygen vacancies and increased leakage current can be compensated by adding excess of bismuth oxide (Park *et al.*, 1994; Wang *et al.*, 2005; Nagata *et al.*, 2006). Note that the vapor pressure of bismuth over $\text{K}_{0.5}\text{Bi}_{0.5}\text{TiO}_3$ (which is close to that of PbO over PZT) is a few orders of magnitude higher than vapor pressures of sodium and potassium over respective niobates (Popović *et al.*, 2015). NBT-BT and NBT-BKT solid solutions reach high relative densities upon sintering at 1050 and 1200°C , respectively (Jo *et al.*, 2012; Kainz *et al.*, 2014; Reichmann *et al.*, 2015; Otoničar *et al.*, 2010).

Solid state synthesis of BZT-BCT takes place at temperatures of about 1200 – 1300°C , and sintering between 1300 – 1500°C . Similar as in the case of pure BT, strict control of stoichiometry is needed to avoid appearance of detrimental secondary phases. Additives or dopants such as CuO , CeO_2 , Y_2O_3 , or Bi_2O_3 were used to reduce the high sintering temperature (Chen *et al.*, 2012; Cui *et al.*, 2012, 2013; Hayati *et al.*, 2016).

Applications

The broad requirements of the various piezoelectric applications are currently being covered by chemically modifying the PZT and up to now no single lead-free composition was identified to fully replace it. However, individual benefits of lead-free systems have attracted the attention of industry and numerous prototypes/devices were reported (Shibata *et al.*, 2018).

Actuators are characterized by displacement, blocking force, and temperature operational range (Webber *et al.*, 2014). Displacement and force are increased by manufacturing multilayered structures. Due to thermodynamic incompatibility, PZT is often limited to the use of expensive Ag or Ag/Pd electrodes, which represent up to 80% of the total material cost (Randall *et al.*, 2005). Lead-free compositions can be co-fired with cheaper base-metal electrodes, such as Ni (Kawada *et al.*, 2009; Liu *et al.*, 2014b) or Cu (Gao *et al.*, 2016b; Yesner and Safari, 2018), which compensate for the costly starting ceramic materials and also have a high electromigration resistance. The displacement of lead-free actuators is inferior to their lead-based counterparts and thus higher driving voltages are required. Despite this, KNN-based actuators for ink-jet printing heads have been reported (Shimosato and Tanuma, 2012; Maruyama, 2008). Benefits of NBT-based actuators include good fatigue resistance (Zhang *et al.*, 2019; Glaum and Hoffman, 2014) and high fracture toughness (Denkhaus *et al.*, 2017), while their drawbacks are the high strain hysteresis and the need for high driving fields.

Sensors transform external mechanical stimuli (pressure, vibrations) into electrical signals and can operate at resonant or off-resonant conditions. The high and temperature-stable electromechanical coupling coefficients (k) of KNN-based compositions made them interesting for sensing, e.g., in knocking sensors, which monitor the combustion in automotive engines (Ohbayashi, 2016). In addition, individual compositions were developed to use the mechanical and thermal external stimuli for electrical power generation (Maurya *et al.*, 2018; Bowen *et al.*, 2014). These electromechanical and pyroelectric energy harvesters are desired for self-powered systems for the Internet of Things.

Transducers are used for ultrasonic imaging, sonars, and high-power applications (cleaning, welding, voltage transformers, etc.). Ultrasonic imaging benefits from the high k , good temperature stability, and low density of KNN-based piezoceramics (Levassort *et al.*, 2011). NBT-based compositions exhibit moderately high Q_m , mechanical stability, and good coupling coefficients. Unlike PZT, their performance does not degrade when driven at high vibration velocities, which enables high ultrasound intensities. They were used in Langevin-type transducers for cleaning (Tou *et al.*, 2009) or for non-destructive evaluation (Edwards *et al.*, 2007), whereas KNN-based compositions were used in ultrasonic motors (Hong *et al.*, 2015). KNN- and NBT-based materials for transducers are now available from several piezoceramic producers.

Over the past 20 years researchers have focused on developing materials with high piezoelectric performance. However, the above-listed prototypes/devices revealed the need for exploring also other application-relevant aspects, including robust processing routes, reproducibility, mechanical and thermal properties, conductivity, lifetime and cost (Koruzza *et al.*, 2018a).

Environmental and Health Concerns

KNN-based solid solutions are considered among the most promising lead-free piezoceramics (Ando, 2012; Coondoo *et al.*, 2013; Gupta *et al.*, 2012; Hao *et al.*, 2019; Hong *et al.*, 2016; Li *et al.*, 2013a; Malič *et al.*, 2015; Rödel *et al.*, 2009, 2015; Safari and Hejazi, 2012; Xing *et al.*, 2018; Wang *et al.*, 2018b; Wu, 2018; Zheng *et al.*, 2018). They are frequently described as “greener” replacements to PZT and reported as environmentally friendly compositions. However, using a systematic, well-established Life Cycle Assessment (LCA), it was recently demonstrated (Ibn-Mohammed *et al.*, 2016, 2017) that the presence of ~60 wt% Nb₂O₅ in KNN constitutes several times greater environmental damage than that of PZT, which occurs due to the methods used for extraction of niobium from its ore and purification processing. Additionally, a cost-benefit analysis of substituting PZT with KNN indicated that the initial cost of conversion to KNN is greater in comparison to PZT, mainly due to higher energy usage during production. Moreover, the authors suggested avoiding the term “environmentally friendly” for the description of KNN and other alternative piezoelectrics, at least until similar LCA studies are conducted to confirm such markings.

NBT, another potential lead-free substitute for PZT, was found to have a lower energy demand during fabrication and therefore a lower overall environmental impact than both PZT and its lead-free competitor KNN (Ibn-Mohammed *et al.*, 2018). However, the environmental profile of Bi₂O₃ precursor was shown to surpass that of PbO used for PZT according to several key environmental indicators, mostly due to additional processing and refining steps required in bismuth production. Moreover, bismuth has a higher energy cost of recycling than lead and over 90% of bismuth is obtained as a by-product of lead smelting (Krüger *et al.*, 2003), which cannot be overlooked from the perspective of potential future upscaling.

Besides environmental concerns, health-related issues of lead-free piezoceramics also need to be addressed before their potential application. For instance, although lead-based piezoceramics have excellent piezoelectric properties, they are not suitable as biomaterials due to their toxicity related to the well-known lead poisoning. On the other hand, clinical trials and in vitro studies showed that bismuth, despite being a heavy element, is not associated with significant toxicity in humans (Serfontein *et al.*, 1979; Rodilla *et al.*, 1998) and NBT–BT and BZT–BCT compositions are currently under investigation as potential biomaterials (Acosta *et al.*, 2018). Similarly, the cytotoxicity of ion-released products from KNN and Li-doped KNN was found to be low (Yu *et al.*, 2011), although slightly higher in the latter due to the release of Li (Yu *et al.*, 2012).

Summary

Triggered by increased environmental awareness and legislations, the research of lead-free piezoceramics has flourished over the past 20 years. Although the three basic material systems were already known for decades, targeted compositional and microstructural engineering has enabled to achieve excellent electromechanical properties, which are for individual compositions

comparable to the state-of-the-art PZT. In addition, this research has enabled to discover new physical phenomena and has considerably increased our understanding of e.g., crystallographic structures, phase boundaries, and relaxors. The reported prototypes and first industrial products are indicative of considerable industrial interest for these materials and continuous efforts are made to exploit the individual benefits of the selected lead-free compositions. Nevertheless, several open questions remain to be addressed in the future, including the reliability and reproducibility, cost reduction and reduction of the environmental footprint.

Electrostrictive Ceramics and Their Applications

Electrostriction

Electrostriction is the ability of all insulator or dielectric materials to develop mechanical deformation if subjected to an electric field. The effect is a consequence of the polarization of the ions inside the material. For insulators in standard condition, the net charge is macroscopically zero. Anyway at atomic level, the crystal is composed of positive (cation) and negative (anion) charged ions. When an electric field is applied through the material, cations and anions rearrange their relative position according to the field itself. As a consequence, the macroscopic size of the material changes. The phenomenological equations of the effect report the electrically induced strain (λ) that is proportional to the squared of the applied electric field (E) or polarization (P). In tensor notation it is expressed as:

$$\lambda_{ij} = M_{ijkl} E_k E_l,$$

or

$$\lambda_{ij} = Q_{ijkl} P_k P_l$$

where, M_{ijkl} ($\text{m}^2 \text{V}^{-2}$) and Q_{ijkl} ($\text{C}^2 \text{m}^{-4}$) are the so-called electrostriction coefficients and they are elements of a fourth-rank tensor, meaning that electrostriction takes place in all crystal symmetries (Li *et al.*, 2014). The subscripts i, j, k, l can be abbreviated for material with isotropic or cubic structure, so it is common to use the Voigt notation: M_{ij} and Q_{ij} with $i, j = 1-4$. As reported in the equations, the strain depends on the squared of the electric field ($\propto E_k E_l$). As a consequence, the distortion always develops in the same direction, regardless of the sign of E or P . Fig. 1(a) shows the parabolic field-induced strain in electrostrictive materials. As depicted in Fig. 1(b), if the applied field is not static but oscillating with a frequency f (the case of AC application), the electrostrictor material oscillates with twice the frequency $2f$ (2nd harmonic). The strain can develop either as a contraction ($M, Q < 0$) or an expansion ($M, Q > 0$), depending on the material. When an object withstands a distortion, it generates a related force or stress σ (N m^{-2}). According to Hooke's law:

$$\sigma = Y \times \lambda$$

where Y is Young's modulus, usually reported in MPa. With the same strain, hard materials with high Y develop higher stress compared to soft materials, such as rubber or polymers.

Electrostriction coefficients M and Q are related by the permittivity properties of the material:

$$M_{ijkl} = Q_{ijkl} \{\epsilon_0 (\epsilon_r - 1)\}^2$$

With ϵ_0 is the vacuum permittivity and ϵ_r is the dielectric constant of the material. The use of one coefficient or another depends on the type of material and formalism. In high permittivity dielectrics that show nonlinear polarization or hysteresis, Q is usually preferred. It is worth noticing that for the same Q value, materials with larger ϵ_r deploy larger strain. As electrostriction comes from a fundamental interaction common in all materials, it can change considerably in both magnitude and dynamics depending on the physical properties of the material. Consequently, electrostriction coefficients range across several orders of magnitude depending on the material itself, with a Q from $10^{-3} \text{ m}^4 \text{C}^{-2}$ for ferroelectrics to $10^3 \text{ m}^4 \text{C}^{-2}$ for polymers (Newnham *et al.*, 1997). Furthermore, while most of electrostrictors such as linear dielectrics, ceramics, and perovskites develop a positive strain (expansion), fluorites and polymers can have the opposite behavior (Sundar and Newnham, 1996; Newnham *et al.*, 1997; Zhang *et al.*, 1998; Li *et al.*, 2014).

In materials that are also piezoelectric, the two effects sum up and the general electromechanical effect is written as:

$$\lambda_{ij} = g_{kij} P_k + Q_{ijkl} P_k P_l$$

With g_{kij} (C m^{-2}) piezoelectric coefficient. Electrostriction can be considered as a second-order contribution of the general electromechanical coupling. Usually, the electrostrictive effect is smaller than the linear contribution by few orders of magnitude. Electrostrictive materials, however, show peculiar characteristics such as low hysteresis in the polarization-strain loop and no remnant strain, making them particularly suitable for high accuracy applications (Uchino *et al.*, 1981; Haertling, 1999; Li *et al.*, 2014).

Application

The ability of electrostrictors to convert an electric signal to mechanical distortion has been extensively used in transducing technologies (Meyer *et al.*, 2001; Restagno *et al.*, 2001; Baek *et al.*, 2011; Jones and Nenadic, 2013; Martin *et al.*, 2014). In particular, an actuator is a transducer which function is to displace an object, working as an electrostrictive motor. Actuators are used in devices that need electrical/mechanical signal conversion such as inkjet printer head, micro-pump, and noise cancellation

Fig. 1 (a) Strain quadratic response to electric field for electrostrictive materials. (b) Electrostriction dynamics under an applied AC field.

systems. A proper actuator should provide a significant displacement with an electric field as low as possible. Also, the performances should be stable and reproducible, allowing fine control of the actuating process. The average strain of a standard actuator is around 10^{-3} . However, this value can be improved in specific engineered devices such as multilayered actuators, or flexensional actuators (CYMBALS) (Haertling, 1999; Meyer *et al.*, 2001; Uchino, 2008). Transducers can also be used in ultrasound imaging and sensors for diagnostic and sonar devices. An electrostrictive ultrasound device can convert electrical signal in mechanical vibration, generating ultra-acoustic waves with extreme accuracy.

Piezoelectric transducers usually have higher performances. Nonetheless, electrostrictors have many advantages over piezoelectrics, such as high accuracy of the strain-field response (no hysteresis or remnant strain), low creep or aging effects, and high speed response (< 10 ms) (Newnham *et al.*, 1997). Also, they can perform at high temperature and frequency. Such features are useful in optical systems such as interferometric dilatometers and deformable mirrors.

In recent years, electrostrictor materials have been frequently included in miniaturized devices known as micro-electro-mechanical systems (MEMS) (Uchino *et al.*, 1981; Uchino, 2008). MEMS applications are several and heterogeneous: Robotics, micro-motors and electronics, biomedical devices. The preference for electrostrictors over piezoelectrics has several reasons. As in small sized devices the electric field increases, the quadratic effect becomes the main contribution to the electromechanical activity. This effect was shown in amorphous silica glass ($M \approx 10^{-21} \text{ m}^2 \text{ V}^{-2}$). In thin films with a thickness lower than $100 \text{ \AA}$, electrostriction strain is higher than piezoelectric contribution (Newnham *et al.*, 1997). This effect can be exploited in the design of materials with a zero-electromechanical coefficient, useful in devices potentially damaged by electric fields. In MEMS, the electroactive material is integrated as thin films and coupled with substrates, usually Si. Piezoelectrics are hard to integrate into these devices, because of high temperature processes and poling needed and diffusion effects often showed for lead-based piezoelectrics.

Both piezoelectric and electrostrictive materials have a limited role in pure medical application, as the best performing materials are lead-based (PZT, PMN). Moreover, these materials have been banned by the RoHS compliant of 2006, due to environmental awareness. For this reason, many efforts have been made in recent years to find a lead-free alternative.

Half of the global market of actuators is focused in MEMS application, followed by phone and digital cameras or lenses (42%), fuel injectors (5%) and ink cartridges (3.3%) (Jo *et al.*, 2012). These data are updated to 2012 when the market value was around 12 millions of dollars, the double respect to 2009 (Jo *et al.*, 2012).

Microscopic Explanation of Electrostriction

When polarized with an electric field, the ions of the material shift from their original position, causing a mechanical strain. The relative displacement of positive and negative ions should erase each other, and the net strain should be null. However, the energy required to compress an ion-pair (U_c) is usually higher than the energy needed to enlarge it (U_e) (Kittel, 2005; Li *et al.*, 2014). This is clear from the ion-pair potential respect to the equilibrium position showed in Fig. 2. Consequently, the polarization usually results in increasing of the ion-pair bond length and a positive electrostriction coefficient. Nevertheless, for some materials such as fluorites, polarization shrinks the ions-pair, causing a negative electrostriction coefficient (Sundar *et al.*, 1996; Newnham *et al.*, 1997). Also, the ion-pair potential varies depending on the material.

Considering a rigid model of $+q$ and $-q$ charged ions, the potential energy function can be described as (Uchino *et al.*, 1984; Sundar and Newnham, 1996; Li *et al.*, 2014):

$$\Delta U = U(r) - U(r_0) = f(r - r_0)^2 - g(r - r_0)^3$$

Where r is the relative distance of positive and negative ions, r_0 is the equilibrium position and f, g represent the harmonic and anharmonic contribution of the energy. Under an electric field, the strain and polarization can be calculated (Uchino *et al.*, 1984; Sundar and Newnham, 1996; Li *et al.*, 2014):

$$\lambda_1 = (3gq^2/4f^3r_0)E_1^2$$

Fig. 2 Ion-pair potential in ionic crystals, r_0 is the equilibrium distance between positive and negative ions.

$$P_1 = (q^2/4\pi r_0^3)E_1$$

As well as the electrostriction coefficient:

$$Q_{11} = 12gr_0^5/fq^2$$

g/f represents the ration between anharmonic and harmonic energy contribution to the overall ion-pair potential. Therefore, high anharmonic component corresponds to high electrostriction coefficient, while f and g are associated with the material microscopic properties such as ionic radius and charge, crystal structure and symmetry. Consequently, compounds with similar microscopic environment show a similar electrostriction magnitude (Warner *et al.*, 1967; Yamada, 1972; Sundar and Newnham, 1996; Sundar *et al.*, 1996; Newnham *et al.*, 1997; Wang *et al.*, 2010; Li *et al.*, 2014).

Thermal Expansion, Newnham's Law, and Materials

In order to describe materials with different anisotropic properties, it is useful to define the hydrostatic electrostriction coefficient Q_h , as the variation of electrical susceptibility with applied hydrostatic pressure. For isotropic or cubic materials, Q_h can be written as:

$$Q_h = 0.5(d\chi/dp) \approx Q_{11} + 2Q_{12}$$

where Q_{11} and Q_{12} are the longitudinal and transverse electrostriction coefficients, respectively. Newnham carried out several studies finding an empirical relationship between macroscopic physical properties and electrostriction coefficients for several kinds of materials (Uchino *et al.*, 1981; Newnham *et al.*, 1997; Li *et al.*, 2014). Electrostriction and thermal expansion both originate from ion-pair potential anharmonicity (Uchino *et al.*, 1981). The thermal expansion coefficient can in fact be written as:

$$\alpha = \frac{3gk_b}{4f^2r_0}$$

With k_b is the Boltzmann's constant and r_0 is the cation–anion distance at equilibrium. Similarly to electrostriction, thermal expansion coefficient α is zero when the anharmonic factor g is 0. Based on Newnham results:

$$\alpha = 4.2 \times 10^{-5} Q_h^{0.5}$$

Thermal expansion and Q_h are related, as both are related to anharmonic ions potential.

Newnham also reported a connection between Q_h and elastic/dielectric effects. As a result, the vast majority of electrostrictive materials follow an empirical relationship:

$$|Q_h| \approx 2.37 \times (S/\epsilon_0 \epsilon_r)^{0.59}$$

Where S is the elastic constant, inverse of Young's modulus. **Fig. 3** shows the logarithm of the electrostriction coefficient, that depends almost linearly on $\log(S/\epsilon_0 \epsilon_r)$. Most of the materials follow this relationship, even if they show very different properties. In **Fig. 3**, we divide the plot into four areas to better group the families of materials. The center of the plot represents materials with high stiffness but low dielectric constant such as linear dielectrics and glass ceramics. The left side includes materials with high dielectric constants such as ferroelectrics and relaxors. On the right side there are polymers, with low permittivity and low stiffness. On the top, defective oxides that share the same properties of linear dielectrics do not follow Newnham's law and show two orders of magnitude higher electrostriction.

Reported with permission from Wachtel, E., Frenkel, A.I., Lubomirsky, I., 2018. Anelastic and electromechanical properties of doped and reduced ceria. *Advanced Materials* 30 (41), 1–17. doi:10.1002/adma.201707455, Copyright 2018, Wiley-VCH.

Linear Dielectrics and Glasses Ceramics

Linear dielectrics are materials which polarization depends linearly on the electric field. They can be single crystals, glasses, or ceramics (Newnham *et al.*, 1997; Yimnirun *et al.*, 2002; Li *et al.*, 2014). These materials usually have low dielectric constant ($\epsilon < 10$) and Young's modulus around $Y \approx 10^2$ GPa. Some examples are CaF_2 single crystal or AlN and ceramics, with $Q_h = 0.47$ and $0.3 \text{ m}^4 \text{ C}^{-2}$ respectively (Newnham *et al.*, 1997; Yimnirun *et al.*, 2002). Some ceramics, such as $\text{BaBi}_2\text{Nb}_2\text{O}_9$ reach high permittivity: $\epsilon \approx 400$ (Adamczyk *et al.*, 2006) and $Q_h = 0.038$ (Li *et al.*, 2014).

Perovskite Ferroelectrics and Relaxor Ferroelectrics

Ferroelectrics are materials with domains that are microscopically polarized in random directions. Like piezoelectrics, it is possible to pole ferroelectrics to enhance their performances. Perovskite ferroelectrics show higher dielectric constant respect to linear dielectrics such as SrTiO_3 ($\epsilon = 450$), PbTiO_3 ($\epsilon = 270$) and BaTiO_3 ($\epsilon = 1070$) but similar Young's modulus. The electrostriction coefficients are $Q \approx 0.04 \text{ m}^4 \text{ C}^{-2}$.

Relaxors is a family of ferroelectrics with diffuse phase transition. They show a high dielectric constant ($\epsilon \approx 10^3$) that depends strongly on both temperature and frequency (Moulson and Herbert, 2003; Heywang *et al.*, 2008; You *et al.*, 2009; Cross, 2011). Relaxor ferroelectrics are generally lead-based perovskites with $\text{Pb}(\text{B}_1\text{B}_2)\text{O}_3$ structure, where B_1 and B_2 are two different ions. These compounds are frequently used as piezoelectrics, but they also possess high electrostriction coefficient. The interest of research and industry started in the 1980 thanks to the first electrostrictive relaxors: $\text{Pb}(\text{Mg}_{1/3}\text{Nb}_{2/3})\text{O}_3$ (PMN), $\text{Pb}(\text{Zn}_{1/3}\text{Nb}_{2/3})\text{O}_3$ (PZN) and $\text{Pb}(\text{La}_{0.09}\text{Zr}_{0.65}\text{Ti}_{0.35})\text{O}_3$ (PLZT) were studied thanks to the promising performances, with a strain up to 0.3% (Haertling, 1999; Uchino *et al.*, 1981; Blackwood and Ealey, 1993; Haertling, 1999; Moulson and Herbert, 2003; Li *et al.*, 2014). The electrostriction coefficients are about $Q_h = 0.002 \text{ m}^4 \text{ C}^{-2}$ and $M = 2 \times 10^{-18} \text{ m}^2 \text{ V}^{-2}$ for PMN (Sundar *et al.*, 1996). Lead-based piezoelectrics and electrostrictors are used in most of the transducer and actuator devices (Jo *et al.*, 2012) in which a combination of massive displacement and high mechanical reliability is needed (Uchino, 2008). Moreover, most of the relaxors are also piezoelectric, and it is possible to combine the two effects (Haertling, 1999). As said, many efforts have been made to introduce lead-free electromechanical materials, and some relaxor alternatives examples are bismuth or niobium based systems (Jo *et al.*, 2012).

Defective Oxides

Gd-doped ceria (CGO) and (Y, Nb)-stabilized $\delta\text{-Bi}_2\text{O}_3$ have been recently reported to possess high electrostrictor behavior, mostly as thin films (Korobko *et al.*, 2012, 2013; Hadad *et al.*, 2016; Santucci *et al.*, 2019). These two materials are both oxides with fluorite structure and a large amount of defects in the form of oxygen vacancies. Being ceramics, their Young's modulus is high: $Y_{\text{CGO}} = 200$ GPa, $Y_{\text{Bi}_2\text{O}_3} = 85$ GPa. They also have low dielectric constants: $\epsilon_{\text{CGO}} \approx 28$, $\epsilon_{\text{Bi}_2\text{O}_3} \approx 26\text{--}30$. The mechanism behind electrostriction in these materials is not the same, and it is related to the local geometry around the oxygen vacancies and their configuration inside grain boundaries (Li *et al.*, 2016; Kabir *et al.*, 2019).

In a pure crystal, one oxygen vacancy forms an octahedron shaped complex with six oxygen atoms. When the field is applied the octahedron withstands a rearrangement including all the oxygen atoms, amplifying the effect. For this reason, the electrostrictive coefficient results particularly high in both materials: $Q_h = 124 \text{ m}^4 \text{ C}^{-2}$ for CGO and $40\text{--}182 \text{ m}^4 \text{ C}^{-2}$ for $\delta\text{-Bi}_2\text{O}_3$. CGO and $\delta\text{-Bi}_2\text{O}_3$ do not follow the trend of Newnham's electrostrictors. Even though possessing the same mechanical/electrical

properties of linear dielectrics in fact, they place two-three orders of magnitude above similar materials. This is attributed to the particular mechanism involving oxygen vacancies. An extensive analysis of other materials with a high amount of vacancies would bring new insight of the effect, maybe showing a new trend for defective oxides.

Although too early for commercial devices, CGO showed good results as membrane and bulk (Mishuk *et al.*, 2017; Ushakov *et al.*, 2017; Kabir *et al.*, 2019). Being a non-toxic and environmentally friendly material, CGO opens new possibilities in high performance bio-compatible and medical application. CGO is also compatible with Si and ceramic electrodes (Santucci *et al.*, 2019) and does not need pre-processing or poling, making it a promising candidate for a new generation of lead-free MEMS.

Polymers

Ferroelectric polymers such as polyvinylidene fluoride (PVDF) and its copolymers, show drastically different mechanical properties respect to ceramics and glasses. Polymers are flexible, with a low density and small Young's modulus ($\approx 10^3$ MPa). They also display a low relative permittivity ($\epsilon \approx 10$) (Newnham *et al.*, 1997). Under an electric field, polymers deploy large strain of the order of 0.25% (Newnham *et al.*, 1997), with resulting electrostriction coefficients around $Q_h \approx 2 \text{ m}^4 \text{ C}^{-2}$. Particular interest has been given to polyurethane, a non-ferroelectric elastomer. Elastomers have usually very low stiffness ($Y = 40$ MPa), that allows these polymers to deploy a high strain response with high electrostriction coefficient of $Q_h \approx 10^3 \text{ m}^4 \text{ C}^{-2}$. Other polymer's properties include frequency dependence field induced strain and high Maxwell stress contribution. In terms of displacement, polymers are comparable with the best relaxor electrostrictors (PMN, PZT) (Yimnirun *et al.*, 2002). Polymers do not generate high stress because of the small Young's modulus, making them difficult to integrate with force related applications. They are however cheap and they comply with complex shapes and surfaces. Polymers are frequently used in composite technology coupled with electromechanical ceramics (Moulson and Herbert, 2003). The properties of the devices are usually engineered to the specific application, and the connectivity between the two materials has a significant role. Composites materials offer advantages in sonar and medical ultrasonic imaging, in which the polymer usually faces soft tissues (Moulson and Herbert, 2003).

Summary

Electrostriction effect is a mechanism that all materials possess and it consists of a mechanical displacement as a response to an electric field. As the strain-field relationship is squared, electrostriction distortion does not depend on the direction of the electric field and happens with twice its frequency. While usually smaller than the piezoelectric effect, electrostriction has some peculiar characteristic useful in applications such as high temperature and frequency operation. Also, electrostrictor materials do not need poling or pre-process to be fully operational. Electrostrictors are particularly suitable for MEMS. For low dimension devices, a higher electric field goes through the material, exploiting electrostrictive behavior more than piezoelectric. Also, electrostriction related strain is highly reproducible and without strain-field hysteresis. That makes electrostrictors valuable in high precision actuators.

Microscopically, electrostriction is due to the anharmonicity of ion pair potential. When the field is applied, the ions rearrange their relative position and are set apart. The species of ion and crystal structure have a major role in the magnitude of electrostriction. Elastic/dielectric properties are also related to the electromechanical activity. Particularly, $\log(Q_h)$ depends almost linearly on $\log(S/\epsilon_0\epsilon_r)$. Most of the electrostrictive materials follow this trend. The most performing materials are lead-based relaxor ferroelectrics, which possess high permittivity and Young's modulus. Polymers are also suitable for particular application thanks to high field induced strain that, however, cannot be converted in stress because polymers low Young's modulus. Defective oxides do not follow this trend: while having mechanical and electrical properties similar to linear dielectrics, they show two-three order of magnitude higher electrostriction coefficient. This is due to a peculiar effect involving oxygen vacancies and a field induced local rearrangement that amplifies the performances.

Low-Loss Ceramics in Mobile Communications

K Wakino and H Tamura, Murata Manufacturing Co., Ltd., Kyoto, Japan

Introduction

Low-loss ceramics in this chapter cover the low-loss dielectric or insulating ceramics for dielectric resonators, multilayer substrates, multichip modules (MCMs), and dielectric antennas. The importance of low-loss ceramics in high-frequency applications is rapidly increasing with the widespread use of these materials for mobile communications, intelligent transportation systems (ITSs), wireless local area networks (LANs), bluetooth systems, etc.

Dielectric Resonator

Dielectric Resonator Material

Study of low-loss and temperature stable dielectric ceramics focusing on microwave applications began in the 1970s, referred to as class I ceramic capacitor materials. The first practically applicable design of a dielectric resonator filter was reported in 1974. A dielectric resonator-controlled local oscillator (DRO; 11–13 GHz) for satellite broadcasting (BS) receiver was introduced in 1975. The advantages of using dielectric resonators include the miniaturization of microwave resonators resulting from the relatively high permittivity of ceramics; very high unloaded Q value owing to extremely low dielectric loss; and high temperature stability of resonant frequencies owing to the small temperature variation of the dielectric constant (O'Bryan *et al.*, 1974; Kawashima *et al.*, 1983; Wakino *et al.*, 1984; Tamura *et al.*, 1984; Zhang *et al.*, 2015; Tyagi, 2014). Moreover, the temperature coefficient of resonant frequency, τ_f , can be optimized by changing the composition of the ceramic so as to compensate for the temperature deviation in the whole system, including the surrounding circuit and components. Much effort has been concentrated on decreasing the dielectric loss of these materials. The origins and mechanism of dielectric loss at microwave and millimeter wave frequencies are discussed in the Section on Dielectric Loss.

Dielectric Properties

To satisfy the low-loss requirements, dielectric resonator materials are basically made of paraelectric ceramics. According to the classical lattice dynamics theory of ionic crystals, the complex permittivity ϵ^* at an angular frequency ω is given by the following dielectric dispersion equation, which is expressed as the superposition of electronic and ionic polarization:

$$\epsilon^*(\omega) = \epsilon(\infty) + \sum_i \frac{4\pi\rho_i \cdot \omega_i^2}{\omega_i^2 - \omega^2 - j\gamma_i\omega} \quad [1]$$

where ω_i , ρ_i , and γ_i are the eigenfrequency, strength, and damping constant, respectively, of the i th IR active lattice vibration modes, and $\epsilon(\infty)$ is the permittivity due to the electronic polarization. The summation is taken over the lattice vibrations in the unit cell. Equation [1] is resolved into real and imaginary parts as follows:

$$\epsilon'(\omega) = \epsilon(\infty) + \sum_i \frac{4\pi\rho_i \cdot \omega_i^2 \cdot (\omega_i^2 - \omega^2)}{(\omega_i^2 - \omega^2)^2 - (\gamma_i \cdot \omega)^2} \quad [2]$$

$$\epsilon''(\omega) = \sum_i \frac{4\pi\rho_i \cdot \omega_i^2 \cdot (\gamma_i \cdot \omega)}{(\omega_i^2 - \omega^2)^2 - (\gamma_i \cdot \omega)^2} \quad [3]$$

As the condition $\omega^2 \ll \omega_i^2$ holds reasonably at microwave and millimeter wave frequencies, and assuming that γ_i is not large, the following approximations are derived from eqns [2] and [3]:

$$\epsilon'(\omega) = \epsilon(\infty) + \sum_i 4\pi\rho_i \quad [4]$$

$$\frac{1}{Q} = \tan\delta = \frac{\epsilon''}{\epsilon'} = \frac{\sum_i (4\pi\rho_i \cdot \gamma_i / \omega_i^2)}{\omega(\infty) + \sum_i 4\pi\rho_i \cdot \omega} \quad [5]$$

$$Q \cdot f = \text{const} \quad [6]$$

Thus, the dielectric constant is independent of frequency and the product of Q and measured frequency is the material constant in the frequency range 10^9 – 10^{11} Hz.

Table 1 Dielectric properties of representative low-loss dielectric materials

Materials	ϵ_r	$Q \times f$ (GHz)	τ_f (ppm °C ⁻¹)	β (ppm °C ⁻¹)
MgTiO ₃ -CaTiO ₃	21	56000	0 ... 6	-0.061
Ba(Sn,Mg,Ta)O ₃	24	240000	0 ... 4	-0.009
Ba(Mg,Sb,Ta)O ₃	24	300000	0 ... 6	-0.009
Ba(Zr,Zn,Ta)O ₃	30	180000	0 ... 6	-0.006

CaTiO ₃ -NdAlO ₃	43	47000	0	
Ba(Sm,Nd) ₂ Ti ₄ O ₁₂	82	10000	-6 ... 6	+0.024
(Ba,Pb)Nd ₂ Ti ₄ O ₁₂	92	5000	0 ... 6	-0.105
(Ba,Pb)(Nd,Bi) ₂ Ti ₄ O ₁₂	110	2500	-2 ... 8	+0.006

**Fig. 1** Frequency dependence of $\tan \delta$ of typical low-loss ceramics at microwave and millimeter wave frequency.

Table 1 lists the dielectric properties of dielectric resonator materials used in practice. **Fig. 1** shows the frequency dependence of $\tan \delta$ from 1 to 35 GHz for representative materials from **Table 1**. As predicted by eqn [5], $\tan \delta$ increases proportionately to frequency. These dielectric properties have been measured by the dielectric resonator method from 1 to 10 GHz (Kobayashi and Katoh, 1985) and by the specially designed TE_{01δ} mode cavity method, shown in **Fig. 2** (Ishikawa *et al.*, 1990), using a non-radiative dielectric waveguide (NRD) (Yoneyama and Nishida, 1981) from 10 to 35 GHz.

The temperature coefficient of resonant frequency, τ_f , is approximated by

$$\tau_f = -\frac{1}{2}\tau_\epsilon - \alpha \quad [7]$$

where τ_ϵ is the temperature coefficient of the dielectric constant and α is the linear thermal expansion coefficient of the dielectric specimen.

Fig. 3 shows the measured temperature dependence of resonant frequency and $\tan \delta$ for representative materials. The term β in **Fig. 3** is the coefficient of the quadratic term in the polynomial expansion equation of permittivity to temperature. Accurately controlled dielectric resonators with desired τ_f values and permittivities between 20 and 95 are available depending on the particular application.

Fig. 2 Test fixture of complex permittivity at millimeter wave frequency.

Fig. 3 Temperature dependence of resonant frequency and $\tan \delta$.

Dielectric Loss

The origin of the intrinsic damping constant γ in eqn [3] comes from the anharmonic terms due to the nonlinear property of the crystal field by which the phonons of IR active modes irreversibly convert to thermal phonons. As the phonon energy follows the Planck distribution, γ is given by (Maradudin and Fein, 1962).

$$\gamma \propto |\phi_3|^2 \times T + \dots \quad [8]$$

Fig. 4 Effect of oxygen vacancy and impurity on $\tan \delta$ of $(\text{Zr,Sn})\text{TiO}_4$.

where ϕ_3 is the third anharmonic term of the Hamiltonian of the crystal. Thus, the dielectric loss tangent increases in proportion to temperature if abnormal phenomena such as phase transition do not occur in the observed temperature range.

Lattice defect is another origin of $\tan \delta$ in addition to the intrinsic anharmonicity of the crystal Hamiltonian. Lattice vacancies and/or inclusions cause a deformation in crystal field and create an anharmonic term in the crystal Hamiltonian. Beside these origins, one has to consider secondary causes such as the influence of grain boundary discontinuity. **Fig. 4** shows the experimental results of investigating the effect of oxygen vacancy and impurity on $\tan \delta$ for $(\text{Zr,Sn})\text{TiO}_4$ dielectric resonator (Maradudin and Fein, 1962; Tamura, 1994). As **Fig. 4** shows, the well-prepared reference sample has the lowest $\tan \delta$ and satisfies the constant $Q \cdot f$ relationship predicted from eqn [5]. When oxygen vacancies of approximately 10^3 ppm are introduced in $(\text{Zr,Sn})\text{TiO}_4$ ceramics by annealing in a reducing atmosphere, $\tan \delta$ increases as much as 0.2×10^{-4} at every frequency, thus $Q \cdot f$ increases at lower frequency. When the specimen is doped with 1.3×10^4 ppm $\text{FeO}_{3/2}$, $\tan \delta$ increases dramatically. An oxygen vacancy and a substituted iron ion have effective charge deviations of $+2e$ and $-e$ ($-e$ is electron charge) from the defect free state, respectively, in a unit cell of $(\text{Zr,Sn})\text{TiO}_4$ crystal (Tamura, 1994; Michiura *et al.*, 1995). The random distribution of these charge defects increases $\tan \delta$ at microwave and millimeter wave frequencies (Schlömann, 1964).

In other words, how perfect the crystal lattice at the grain and space-charge free grain boundary is, is a key factor in manufacturing low-loss ceramics. Prolonged sintering over 100 h improves the Q value owing to the formation of a well-ordered superlattice structure (Kawashima *et al.*, 1983).

Applications

Dielectric resonator

Fig. 5 shows the structure and electromagnetic field distribution of the most commonly used three dominant modes (TEM, TM_{010} , and $\text{TE}_{01\delta}$) for dielectric resonators.

The TEM mode dielectric resonator is characterized by a coaxial waveguide mode field distribution with standing wave of a quarter wavelength. This mode dielectric resonator provides the most significant size reduction effect but the highest degradation of unloaded Q of the three modes.

The TM_{010} mode dielectric resonator is characterized by a TM mode field distribution along the resonator axis. This mode resonator has medium levels of unloaded Q and size reduction effect, between that of the $\text{TE}_{01\delta}$ and TEM mode resonators.

The $\text{TE}_{01\delta}$ mode dielectric resonator is characterized by a dominant TE mode field distribution, the field of which leaks at both ends of the resonator in the direction of wave propagation with rapid attenuation. Since the $\text{TE}_{01\delta}$ mode resonator has no directly attached conductor, the highest unloaded Q can be achieved using this mode.

Fig. 5 Schematic structure and electromagnetic field distribution of three dominant modes TEM, TM_{010} , and $TE_{01\delta}$.

Fig. 6 Schematic structure of antenna duplexer for a mobile telephone.

Total unloaded Q , Q_u , is broken down as follows:

$$\frac{1}{Q_u} = \frac{1}{Q_d} + \frac{1}{Q_c} + \frac{1}{Q_r} \quad [9]$$

where Q_d , Q_c , and Q_r are Q factors from dielectric loss, current loss, and radiation loss, respectively. Practically, the loss owing to radiation can be neglected when the resonator is enclosed in a metallic case.

Antenna duplexer of portable telephones

Fig. 6 shows an example of an antenna duplexer. To realize the ultimate miniaturization of the device, the quarter wavelength TEM mode dielectric resonator is preferably used for this application.

Fig. 7 Frequency dependence of unloaded Q of $\lambda/4$ TEM mode DR with 3 mm diameter.

Fig. 8 TM_{010} dual-mode power filter for cellular base station.

With small-size TEM mode resonators, a large proportion of power loss comes from current loss. **Fig. 7** shows the unloaded Q of a $\lambda/4$ TEM mode dielectric resonator with an outer diameter of 3 mm. In the calculation of copper loss, the conductivity of $\sigma = 4.8 \times 10^7 \text{ Sm}^{-1}$ (approximately 80% of bulk value) is chosen, which is practically guaranteed by the firing of silver paste or by electroless copper plating.

To realize the miniaturization of filters with longer wavelength of 900 MHz band antenna duplexer, the high dielectric constant materials $(\text{Pb,Ba})\text{Nd}_2\text{Ti}_4\text{O}_{12}$ or $\text{Ba}(\text{Bi,Nd})_2\text{Ti}_4\text{O}_{12}$ with ϵ_r of 90 are widely used. For the shorter wavelength 2 GHz band, medium dielectric constant (from 20 to 40) with lower loss materials are used to obtain higher unloaded Q .

Filters in cellular base stations

With regard to the power filters for cellular base stations, as low as possible dielectric loss and nonlinear dielectric properties are required so as to prevent heat generation and interference between signal channels.

Fig. 8 shows an antenna duplexer for a cellular base station using TM_{010} dual-mode dielectric resonators (Ishikawa *et al.*, 1992). This filter can be applied for high-power operation with the help of heat transportation to the metal cavity through directly applied electrodes on the ends of the resonator body.

$(\text{Zr,Sn})\text{TiO}_4$, $\text{CaTiO}_3\text{-NdAlO}_3$, and $\text{Ba}(\text{Zr,Zn,Ta})\text{O}_3$ are used for these applications, as these materials satisfy the high ϵ_r , high Q value, and low distortion requirements.

Fig. 9 shows the measured result of the intermodulation level owing to third harmonic distortion at 800 MHz (Nishikawa *et al.*, 1989; Tamura *et al.*, 1989a). The distortion level of $(\text{Zr,Sn})\text{TiO}_4$ material is better than -140 dBc at a field intensity of $6 \times 10^4 \text{ Vm}^{-1}$, which is applicable without cross-talk problems to the filters in cellular base stations with an maximum input power of 500 W.

Millimeter wave applications

Although their dielectric constants are not very high, the complex perovskite materials based on $\text{Ba}(\text{Zn,Ta})\text{O}_3$ and $\text{Ba}(\text{Mg,Ta})\text{O}_3$ have very high Q values suitable for millimeter wave applications. **Fig. 10** shows the TE_{010} mode dielectric filter with central frequency of 30 GHz (Ishikawa *et al.*, 1997). The TE_{010} mode resonator is made of $\text{Ba}(\text{Sn,Mg,Ta})\text{O}_3$ pore-free substrate with $\epsilon_r = 24$ and has an unloaded Q of 1600.

Fig. 9 Third harmonic distortion vs. electric field for low-loss ceramics.

Fig. 10 Schematic structure of 30 GHz TE₀₁₀ mode filter.

Materials for high-temperature superconductivity

Much effort has been made to realize microwave filters for cellular base stations by using high-temperature superconductors. YBa₂Cu₃O_{7- δ} (YBCO) thin films on LaAlO₃ substrates are used for these applications. As shown in Fig. 11, Ba(Sn,Mg,Ta)O₃ has an extremely high $Q \cdot f$ value of 10⁶ GHz at 70 K (Tamura *et al.*, 1989b), so that this material is a promising candidate as a temperature-stable and ultralow-loss substrate for microwave circuit incorporation with high-temperature superconductors.

Fig. 11 $\tan \delta$ of ultralow-loss ceramics at cryogenic temperature.

Fig. 12 Comparison of surface resistivity of Bi2223 thick film and YBCO thin film.

Fig. 12 shows the comparison of surface resistance at 10 GHz between YBCO thin film and Bi2223 thick film (Tatekawa *et al.*, 1999). Although the surface resistance obtained for Bi2223 thick films is not sufficiently low owing to the imperfect *c*-axis alignment, it has the possibility for future improvement.

Ceramic Substrates

Low-Temperature Co-Fired Ceramics

Since the major portion of power loss in high-frequency circuits is generated by current loss, owing to the finite electrical conductivity and skin effect, high conductivity metals such as silver ($6.3 \times 10^7 \text{ Sm}^{-1}$) or copper ($6.0 \times 10^7 \text{ Sm}^{-1}$) are preferred as electrode materials. Difficulties in the use of silver or copper as co-fired electrode materials are derived from their relatively low melting temperatures (silver, 962 °C; copper, 1083 °C) compared to the sintering temperature of commonly used dielectric ceramics (1300–1450 °C); another serious problem is that copper is easily oxidized during sintering in ambient atmosphere.

To overcome these difficulties, various kinds of low-temperature firable and nonreducible ceramics (so-called low-temperature co-fired ceramics, LTCCs) have been developed and put into practical use. LTCC materials can be classified (1) concerning the basic material (e.g., glass-added system and nonglass system; and (2) concerning the conductor material (e.g., copper system and silver or silver/palladium system).

Although addition of a sintering agent or glass degrades the dissipation factor and thermal conductivity somewhat, if the materials are carefully chosen, the deterioration of loss tangent can be kept within acceptable limits. Since Q_c (Q value owing to current loss) is 300–400 at most between 1 and 2 GHz, $Q_d(1/\tan \delta)$ of 1000 or more is practically applicable. Poor thermal conductivity applies some limits for high-power devices, but in practice there is no limit for low-power signal applications.

Tables 2 and 3 summarize the representative properties of several LTCC materials of several manufacturers. For miniaturization, especially at lower frequency, relatively high dielectric constant material is preferred, whereas for a high speed and/or a less distortion transmission line, lower dielectric constant material is favored. Matching of thermal expansion coefficient of substrate and the devices on that substrate should be taken in account to minimize the residual stress on relatively large devices. A good match of thermal expansion coefficient is an important factor for flip chip bonding of LSI.

Multilayer Devices Using LTCCs

Although LTCC devices, such as multilayer semidistributed LC filters, 90° couplers, power dividers, and balun, are not so highly intelligent, these simple devices are gaining favor and play important roles in sophisticated systems as key functional devices of small size, lightweight, and tuning free. Fig. 13 shows schematically the structure and the equivalent circuit of a 3 dB coupler. The structure and performance of a 5.8 GHz LC filter for the latest electronic toll collector (ETC) system are shown in Fig. 14. The dimensions of this device are 2.0 mm × 1.5 mm × 1.0 mm.

MCM

For further integration and greater miniaturization, a number of devices are combined in a multilayer substrate structure, a so-called MCM. Several grades of integrated modules with few or many devices, including ICs, are in production and contributing to miniaturization and increasing the intelligence of modules.

In analog systems, dielectric resonator duplexers have been mainly used for the antenna filter, but in a digital system, like GSM, the diode switcher can be used instead of the DR duplexer. The diode switcher has the advantages of being lighter, smaller, and cheaper than the DR duplexer. Therefore, almost all GSM cellular telephones use the diode switch. As a low-pass filter, a combination of strip lines and capacitors is embedded in the multilayer ceramic substrate, and two diodes and one resistor are mounted on the top of substrate. For active devices, silicon bare chips are mounted on the ceramic surface with die adhesive and connected with wire bond technology, or silicon flip-chip is mounted using flip-chip bonding technology. Beside these, filters and other peripheral circuits are integrated in the ceramics.

Fig. 15 shows schematically the basic concept of future three-dimensional integration by MCM.

Dielectric Antenna

Several types of distinctive antennas are now in use. By choosing an appropriate shape, size, and configuration of ceramic and conductor, dielectric antennas with acceptable characteristics can be designed for desired working frequencies. Fig. 16 shows a microstrip antenna (or patch antenna) for a global positioning system (GPS) receiver, using a high K dielectric substrate. Dielectric ceramic loaded stripline antennas have several advantages, namely small size, fairly narrow but still wide enough frequency band, and good temperature stability. GPS receivers are required to receive multiple signals from three or four different satellites

simultaneously. This antenna has axially symmetric gain characteristics around the vertical axis, so that this antenna is suitable as a multidirectional antenna.

Figs. 17 and **18** show the schematic structure and directivity data of dielectric chip antennas for mobile telephone terminals, respectively. The gain is slightly lower than that of the conventional whip antenna (so called pig-tail antenna), but it is high enough for microcell systems. This type antenna is expected to be the key device for the future miniaturization of short-range applications such as microcell handsets, small office or home LAN systems, Blue Tooth, etc.

Ceramic Capacitors

Single-Layer (Microchip) Capacitor

Most of the classical lead-type ceramic capacitors have been replaced with chip-type ones since the popularization of surface mount technology (SMT). The advantages of the chip-type over the lead-type capacitor are that it is smaller, lighter, and is better fitted to the requirement of surface mount devices (SMDs). SMT meets the demands for fully automated, flexibly controlled by computer, and much faster (less than 0.1 s per component) assembling of miniaturized equipment. Furthermore, a great advantage of chip-type components is that the parasitic inductance and stray capacitance can be reduced dramatically based on the extremely small electrode and leadless structure. Small size and less parasitic characteristics are quite effective for high-density assembling of microwave and millimeter wave equipment. In this chapter the description of lead-type devices is omitted for these reasons.

For very high frequency application, attention should be paid to the self-resonance phenomena of the capacitor and/or to the complex coupling with neighboring circuit and components. Sometimes, even a quite small inductance of signal line will cause unwanted resonance problems owing to the formation of serial or parallel parasitic LC connections in microwave or millimeter wave circuits. The lowest self-resonant frequency of a plate-type capacitor is roughly estimated by the following equations (TM_{010} mode or capacitor mode):

Fig. 17 Example of dielectric chip antenna.

Fig. 18 Directivity data for dielectric antenna mounted on handset.

$$f_r \approx \frac{1}{2\sqrt{\epsilon_r}} \cdot \frac{c}{a} \text{ for a rectangular capacitor}$$

$$f_r \approx \frac{J_0(r)}{2\sqrt{\epsilon_r}} \cdot \frac{c}{r} \text{ for a disk - type capacitor}$$

where a , r , c , and $J_0(r)$ are the length of the longer side of the rectangular electrode, radius of the electrode of a disk capacitor, velocity of light in free space, and the first root of the first kind of Bessel function, respectively.

Since the values of $\tan \delta$ of class I ceramic capacitor materials are small enough (see Table 1) and the loss at very high frequency is largely defined by the current loss in the electrode rather than dielectric loss, the improvement of intrinsic dielectric loss is not such a critical issue for the capacitor, unlike for the dielectric resonator.

Fig. 19 shows schematically the structure of a microchip capacitor. The multielectrode array of binary aerial series is specially designed for convenience of tuning after assembling. Direct bonding to the ground plane can guarantee minimum parasitic inductance. As shown in Fig. 20, the small capacitance microchip capacitor does work over 10 GHz.

Fig. 19 Structure of microchip capacitor.

Fig. 20 Frequency characteristics of microchip capacitor.

Multilayer Ceramic Capacitor

The basic structure of an multilayer ceramic capacitor (MLC) is shown in Fig. 21. High capacitance is achieved by thin and multistacked dielectric layers, even with a small footprint. Neglecting the fringing effect, the capacitance with the given fixed effective shape and size is proportional to $1/t_1 \times (t_1 + t_2)$, where t_1 and t_2 are the thickness of the dielectric and electrode, respectively. The thickness of the active layer approaches 1–2 μm .

Originally, MLC manufacturing used platinum or palladium electrodes at the beginning of the 1940s to adapt to high-temperature and normal-atmosphere sintering. Subsequently the Ag–Pd electrode has been introduced to reduce the material cost of electrode. Since the early 1980s the electrode material is has been nickel or copper for further reduction of material cost even with the increase of processing cost for nonoxidizing sintering. Copper has the additional advantage of having higher electrical conductivity that is favorable for high Q and high-frequency applications.

Fig. 21 Sketch of basic structure of an MLC.

Table 4 Comparison between precious metal and base metal multilayer ceramic capacitors

Electrode	Material	Pt	Pd	Ag-Pd	Ag	Ni	Cu
	Melt. temp. (°C)	1500	1450	1350	940	1500	1040
	Fire. Atm.	Air	Air	Air	Air	N ₂	N ₂
Dielectric	Material	Normal	>	>	>	Non-reducing	>
Q		Excellent	Excellent	Good	Good	Fair	Good
Ins. resit.		Excellent	Excellent	Good	Good	Fair-Good	Fair-Good
Reliability		Excellent	Excellent	Good	Fair	Good	Good

Fig. 22 Comparison of s-parameters between vertical and horizontal placing.

Table 4 summarizes the characteristics and features of different types of MLC.

As is seen in **Fig. 22**, it is worth noting that the s-parameter is different between two states; the inner electrode is placed parallel to the substrate and vertical for microwave or millimeter wave application.

Small-Scale Energy Harvesting Devices for Smart Electronics

Sumanta Kumar Karan, Rammohan Sriramdas, Min-Gyu Kang, Yongke Yan, and Shashank Priya, Pennsylvania State University, University Park, PA, United States

Introduction

Novel power sources play a crucial role in the advancement of the new generation of electronic applications. Emerging small-scale modern electronic devices are lightweight and portable and have an emphasis on utilizing renewable power sources to provide sustainable solutions that have lasting user impact (Goldemberg, 2007; Wang and Song, 2006; Priya and Inman, 2009). On a large scale, geothermal, solar, nuclear, biomass, hydrogen, and wind energies are being developed as efficient renewable energy sources (Karan *et al.*, 2016). On a smaller scale, the rapid development of the internet of things (IoT) has generated tremendous number of microelectronic devices and wireless sensors that have multiple functionalities, wide-spread availability, and network connectivity (Atzori *et al.*, 2010; Gershenfeld *et al.*, 2004). In these applications, traditional power supplies based on batteries have limited lifetime, which results in a high cost of maintenance and replacement. To address this limitation, ambient energy harvesting devices based upon natural sources such as solar, thermal, magnetic field, vibrations, and bio-fuel energies have received attention to provide sustainable power sources.

Mechanical energy, including human body movements, various acoustic and vibration sources, and air/water flows are relatively abundant in our environment. These kinds of random mechanical energies are suitable for development of energy harvesters which are continuously interacting with the environments. It is advantageous to adopt a suitable energy harvesting technology depending upon the available form of energy. Different mechanical energy sources available in our surrounding useful to harvest electrical energy are summarized in Table 1.

Piezoelectricity and triboelectricity are two major energy conversion mechanisms to efficiently convert various types of wasted mechanical energies into electricity. Recently, piezoelectric nanogenerators (PENGs) (Fan *et al.*, 2009; Priya, 2007; Chung *et al.*, 2012) and triboelectric nanogenerators (TENGs) (Liu *et al.*, 2019b; Karan *et al.*, 2020) are gaining interest for energy harvesting applications, because of their reasonable energy conversion efficiency, which makes them an attractive power source for smart electronics, active sensors, and in-vivo electronic health (e-health) care (Maiti *et al.*, 2019). Magnetic fields are a ubiquitous energy source available in our surroundings with 50/60 Hz parasitic magnetic noise arising from electric power transmission cables, electronic devices, subways, manufacturing machines, etc (Ryu *et al.*, 2002; Lee *et al.*, 2020). However, the amplitude of the magnetic field strength around these sources is very low, typically less than 1 mT = 10 G. For magnetic field energy harvesting, therefore, novel approaches are required to efficiently convert low frequency and low strength magnetic fields into high electrical power. Magneto-mechano-electric (MME) generators have attracted great interest because of their capability to generate high power density from low-frequency magnetic fields (Kang *et al.*, 2018). Energy harvesting devices can capture energy from low-frequency mechanical vibrations and weak magnetic fields, based on the piezoelectric effect, triboelectric effect, and the magneto-mechano-electric effect. Device demonstrations with high efficiency and power density will enable advancement of small and smart portable electronics for wireless sensors, data transfer, and biomedical applications (Fig. 1). In the last decade, many efforts have been made towards development of novel energy harvesters that can convert small magnitude of mechanical or magnetic energy into usable electricity for powering standalone electronic systems (Wang *et al.*, 2007; Sriramdas *et al.*, 2020). However, in practice, the size of these generators should be as small as possible for ease of installation in smart electronics applications. Considering this scenario, we have focused our discussion on small-scale energy harvesting devices that have been reported in literature. The general principle for conversion of low frequency mechanical stress into electrical energy using piezoelectric/triboelectric energy harvesters is shown schematically in Fig. 2. The conversion of magnetic field to electric energy using magneto-mechano-electric energy harvester is also discussed. We illustrate the key parameters that should be taken into account for developing high performance small scale PENG/TENG/MMEG devices.

We begin with a brief overview on the importance of input energy parameters for coupling of the mechanical/vibration/magnetic field into electricity and types of constituent materials. Next, a discussion is provided on the material parameters (such as piezoelectric coupling constants d and g , electromechanical coupling factor k , triboelectric charge density Q , magnetostriction λ , etc.), elastic coupling occurring between the piezoelectric and magnetostrictive phases and fundamental properties which

Table 1 Different available mechanical energy sources to harvest electricity

ultimately influence the electrical properties. After that we describe the device structure for energy harvesting for various types of harvesters, output performance, impedance matching requirements and some potential applications. The power density of a harvester is dependent upon the strategies that maximize the energy capture and reduce the losses occurring at each step, namely, mechanical loss due to mismatch in mechanical impedance, and electromechanical loss depending upon the magnitude of the coupling factor. Three significant stages of energy transduction common to all the generators are: (1) transfer of input stimuli in the form of mechanical motion/magnetic field from ambient source, (2) conversion of the input energy into electrical form by direct piezoelectric/triboelectric effect in PENG or TENG and magnetic field to mechanical strain and then to electrical energy in MMEG, and (3) power management and storage of the generated electrical energy. The chapter concludes with a brief summary and future perspectives.

Transduction Mechanism

Fundamentals of Piezoelectricity

Piezoelectricity is the ability of certain crystalline materials that possess non-centrosymmetry (point group lacks an inversion center) to develop an electric charge proportional to the applied mechanical stress (direct piezoelectric effect) or develop a mechanical strain (deformation) proportional to an applied electric field (converse piezoelectric effect) (Damjanovic, 1998). According to Neumann's principle, the symmetry elements of any physical property of a crystal must include the symmetry elements of the point group of the crystal (Nye, 1985; Newnham, 2005). Piezoelectric property can exist only in 20 non-centrosymmetric point groups. Of the 20 piezoelectric point groups, 10 point groups show the presence of spontaneous polarization (electric polarization that a substance possesses in the absence of an external electric field). These materials are termed as pyroelectric materials, in which the magnitude of the polarization varies with change in temperature. All ferroelectric crystals belong to one of these 10 polar point groups. Ferroelectrics are a subgroup of the pyroelectric family that exhibit at least two equilibrium orientations of the spontaneous polarization in the absence of an external electric field. The spontaneous polarization can be switched between the two orientations by applying an electric field (Damjanovic, 1998). It should be noted here that as-synthesized ferroelectric materials, either in the form of grain oriented polycrystalline thin films and bulk ceramics or single crystals, do not exhibit piezoelectric and pyroelectric response. The reason is that as-sintered ferroelectric ceramic or as grown thin film and single crystals usually contain randomly oriented domains. The piezoelectric effect of individual domains will cancel each other resulting in net zero polarization. Ferroelectric domains are formed below the Curie temperature in order to minimize the electrostatic energy of depolarizing fields and the elastic energy associated with mechanical constraints. Thus, ferroelectric materials need a strong electric field to induce the polar state by aligning the domains along the applied field direction (as mentioned earlier, poling process).

When the mechanical stress is applied to a piezoelectric material, an electric charge proportional to the applied stress is produced. This refers to the direct piezoelectric effect. Conversely, when electric field is applied to the same material, strain or displacement is produced proportional to the magnitude of electric field. This is called as converse piezoelectric effect. The direct piezoelectric effect can be effectively applied for an energy transducers/sensors, and the converse piezoelectric effect can be applied for the design of actuators. The general working approaches are schematically shown in Fig. 3(a)–(c). Fig. 3(a) represents the original state of the piezoelectric materials under the poling condition. The direct and converse piezoelectric effect of the piezoelectric materials is expressed by two different linear constitutive equations: (Kim *et al.*, 2011)

$$\text{Direct piezoelectric effect: } D_i = e_{ij}^{\sigma} E_j + d_{im}^d \sigma_m \quad (1)$$

$$\text{Converse piezoelectric effect: } \varepsilon_k = d_{jk}^c E_j + S_{km}^d \sigma_m \quad (2)$$

where the vector D_i signifies the dielectric displacement (unit in N/mV or C/m²), ε_k denotes the strain vector, E_j represents the applied electric field vector (unit in volts/meter), and σ_m stands for stress vector (unit in N/m²). The piezoelectric constants are the piezoelectric coefficients d_{im}^d and d_{jk}^c in m/V or C/N, the dielectric permittivity e_{ij}^{σ} in N/V² or F/m, and S_{km}^d signifies the elastic compliance matrix in m²/N. The superscripts c and d in the equation represent the converse and direct effects, respectively, and the superscript E and σ in the equation mean that the quantity is measured at constant stress and constant electric field, respectively.

The piezoelectric coefficient values can be either positive or negative, which can be calculated/measured in the direction of the applied field, well-known as the longitudinal piezoelectric coefficient, or it can be estimated in the perpendicular direction to the applied field, known as a transverse coefficient. Another piezoelectric coefficient of interest is the shear coefficient (Araujo and Soares, 2009). Since the stress and strain are symmetrical tensors, thus, the piezoelectric coefficient tensor is symmetrical in nature with respect to the same indices. In general, for longitudinal piezoelectric constant represented as d_{ij} , the subscript "i" represents the applied electric field or charge collection direction, and "j" represents the displacement or force or pressure direction. The

Fig. 3 Working mechanism of piezoelectric material. (A) poling process for polarizing piezoelectric materials, (B) direct piezoelectric effect, and (C) converse piezoelectric effect.

relationships for piezoelectric constants are given as:

$$d_{ij} = \left(\frac{\partial D_i}{\partial T_j} \right)^E = \left(\frac{\partial S_j}{\partial E_i} \right)^T \quad (3)$$

$$e_{ij} = \left(\frac{\partial D_i}{\partial S_j} \right)^E = - \left(\frac{\partial T_j}{\partial E_i} \right)^S \quad (4)$$

$$g_{ij} = - \left(\frac{\partial E_i}{\partial T_j} \right)^D = \left(\frac{\partial S_j}{\partial T_i} \right)^T \quad (5)$$

$$h_{ij} = - \left(\frac{\partial E_i}{\partial S_j} \right)^D = - \left(\frac{\partial T_j}{\partial D_i} \right)^S \quad (6)$$

where the first set of four terms indicates the direct piezoelectric effect and the second set of four terms represents the converse piezoelectric effect (Arnaú and Soares, 2009). There are five important material parameters for the design of piezoelectric material based applications: the piezoelectric strain constant d , the piezoelectric voltage constant g , the electromechanical coupling factor k , the mechanical quality factor Q_m , and the acoustic impedance Z (Uchino, 2010a; Zhang and Li, 2012). Each of these parameters are defined below.

Piezoelectric strain constant d : The magnitude of the induced strain x by an external electric field E is represented as: $x = dE$. The magnitude of d is an important consideration for actuator applications.

Piezoelectric voltage constant g : The induced electric field E is related to applied external stress X through the piezoelectric voltage constant g (an important figure of merit for sensor applications): $E = gX$.

Electromechanical coupling factor k : The electromechanical coupling factor k of a piezoelectric material refers to the efficiency of conversion between electrical and mechanical energy and vice-versa. This parameter is closely related to the bandwidth of resonant devices.

Mechanical quality factor Q_m : For a piezoelectric resonator, the mechanical quality factor Q_m characterizes the resonator's bandwidth relative to its center frequency: $Q_m = f_r/\Delta f$, where f_r is resonance frequency, and Δf is the frequency difference at -3 dB of the maximum admittance. A high Q_m is important for resonant applications while high Q_e (inverse of dielectric loss) is crucial for off-resonance devices.

Acoustic impedance Z : The acoustic impedance Z of a material is also related to the elastic constant and/or phase velocity through the relationship: $Z = \sqrt{\rho c}$, where ρ is the density and c is the elastic stiffness of material. Analogous to electrical impedance, the transfer of acoustic energy from one medium to another will be maximized when the two media have the same acoustic impedance.

Besides piezoelectric properties, dielectric properties are also very important in designing piezoelectric device. Dielectric constant (ϵ_r), dielectric loss ($\tan\delta$) and Curie temperature (T_c) are the most commonly characterized parameters. Dielectric constant (ϵ_r) is important for the device performance, since the capacitance is closely related to electrical impedance. Dielectric loss ($\tan\delta$) is the dissipation of energy in the form of heat. Low $\tan\delta$ is very important for high power device and sensor application. Curie temperature (T_c) represents the point above which the crystal structure becomes symmetrical and the material becomes non-piezoelectric. This point represents the maximum operating temperature for piezoelectric materials. Ferroelectric materials can be characterized by measuring their polarization as a function of applied ac electric field (P - E hysteresis loop). Remnant polarization (P_r) refers to the polarization that remains when the electric field is removed, and Coercive field (E_c) is the electric field required to reduce the polarization to zero. High E_c implies the need for high electric field to pole the sample, while low E_c materials may have low electrical stability as they can be easily depolarized.

There are mainly two approaches to achieve enhanced electric, ferroelectric and piezoelectric properties: (1) composition selection and modification through substitution/doping, and (2) microstructural design. Composition selection approach focuses on identifying binary and ternary phase diagrams that offer unique boundaries. The composition modification focuses on doping and substitutions in order to tailor the defect chemistry and phase transitions. The microstructure design focuses on the optimization of grain size and distribution, grain orientation or texture, domain size and defect organization.

Types of piezoelectric materials

Ceramic-based piezoelectric materials

The discovery of barium titanate (BaTiO_3), lead zirconate titanate ($\text{Pb}(\text{Zr}_{1-x}\text{Ti}_x)\text{O}_3$, known as PZT), and the family of materials based on these formulations, was a major breakthrough in advancing research on piezoelectric materials (Kwon et al., 2012). The PZT solid solutions with morphotropic phase boundary (MPB) have been dominating the piezoelectric industry since their discovery in 1950. MPB is an intrinsic region of a phase diagram where two or more phases coexist. The solid solution of piezoelectric materials having MPB shows enhanced piezoelectric and dielectric responses at this phase boundary. For example, the phase diagram of PZT has PbTiO_3 and PbZrO_3 as end members (Jaffe et al., 1971). Traditionally, the high piezoelectric response has been attributed to the enhanced number of polar axis in MPB composition. In a particular crystallographic symmetry, there are always a fixed number of equivalent polar axes in which the dipoles can be switched. The Ti-rich side of MPB in PZT possesses the tetragonal crystal symmetry with 6 equivalent $[001]$ directions as polar axes. However, on the Zr-rich

side of the MPB, PZT with rhombohedral symmetry possesses 8 equivalent [111] directions as polar axes. Because at MPB two different phases coexist, the switching of polar axes in PZT has 14 available directions under applied E-field. This phenomenon was considered to be responsible for giving rise to high piezoelectric response at MPB. [Noheda et al. \(2000\)](#) identified the presence of bridging monoclinic phase between tetragonal and rhombohedral phase around MPB of PZT. Some well-known piezoelectric materials having MPB are $(1-x)\text{Pb}(\text{Mg}_{1/3}\text{Nb}_{2/3})\text{O}_3$ - $x\text{PbTiO}_3$, $(1-x)\text{Pb}(\text{Zn}_{1/3}\text{Nb}_{2/3})\text{O}_3$ - $x\text{PbTiO}_3$, and $(\text{Na}_{0.5}\text{Bi}_{0.5})\text{TiO}_3$ - BaTiO_3 . High resolution X-ray diffraction investigations suggest that the major intrinsic contribution from both rhombohedral and tetragonal phase comes from the tilting of the P_s vectors ([Hoffmann et al., 2005](#)). The monoclinic phase with 24 permitted orientation states is expected to provide bridging polarization continuity leading to enhanced piezoelectric response ([Hoffmann et al., 2005](#)). Finding morphotropic phase boundary in a solid solution of piezoelectric materials is one of the important method to achieve high piezoelectric response. In addition, it has been shown that enhanced piezoelectric response can be related to the presence of miniaturized ferroelectric domains ($< 1 \mu\text{m}$) with high mobility ([Wada et al., 2005](#)). Wada et al. were able to synthesize miniaturized domain structure in BaTiO_3 single crystal by applying E-field along non polar [111]_c direction through a poling process conducted above T_c ([Wada et al., 2005](#)). The high piezoelectric response ($d_{31} = -230$ pC/N) observed in this system was attributed to the high density of domain walls ([Wada et al., 2005](#)). Wang et al. have performed theoretical calculations and confirmed that the enhanced piezoelectric response in the specimen with miniaturized domains was correlated with domain wall broadening under applied E-field ([Rao and Wang, 2007](#)). The enhanced piezoelectric response in non-polar directions was believed to be originated from the broadening of domain walls. Furthermore, the doping (soft and hard) of various elements in PZT has been effectively used to tune the piezoelectric response. The doping of elements like Nb^{5+} or Ta^{5+} (donor) results in “soft” PZTs (e.g., PZT-5). The enhanced piezoelectric response in soft PZT has been attributed to the ease in domain wall motion due to doping induced Pb vacancies ([Uchino, 2010b](#)). The acceptor type dopant (e.g., Fe^{3+} or Sc^{3+}) gives rise to “hard” characteristics as exemplified by PZT-8 ([Uchino, 2010b](#)). The hard PZTs have low piezoelectric response but high mechanical quality factor Q_m . This behavior of the hard PZTs has been attributed to the pinning of domain wall motion due to the presence of the doping induced oxygen vacancies ([Uchino, 2010b, 2009](#)). **Table 2** summarizes the piezoelectric, dielectric and elastic properties of typical PZTs: soft PZT-5H, semi-hard PZT-4, and hard PZT-8. Note that soft PZTs exhibit high electromechanical coupling (k), high piezoelectric coefficient (d), high relative permittivity, in comparison with hard PZTs, while Q_m is quite high in hard PZTs. Thus, soft PZTs should be used for off-resonance applications, while hard PZTs are suitable for on-resonance applications.

Lead-free perovskite materials have recently gained much attention due to the significant improvement in their physical properties. High piezoelectricity ($d_{33} \approx 416$ pC/N) was found in lead-free $(\text{K},\text{Na})\text{NbO}_3$ (KNN)-based textured ceramics having orthorhombic-tetragonal (O-T) phase boundary, which was fabricated using a reactive template grain growth (RTGG) method ([Zhang et al., 2015](#)). A series of KNN-based ceramics were demonstrated with high piezoelectric constants ($d_{33} = 490$ – 570 pC/N) by designing mixed-phase boundaries of rhombohedral (R) and tetragonal (T) phases ([Wang et al., 2018](#)). Continued investigations on the KNN-based textured ceramics have improved piezoelectric coefficient d_{33} to 700 pC/N with a large electro-mechanical coupling factor (k_p) value of 0.76 ([Moriana and Zhang, 2018](#)). Further, BT-based polycrystalline ceramics have shown a higher piezoelectric coefficient as compared to other lead-free piezoceramics. Ren et al. demonstrated a large piezoelectric coefficient ($d_{33} \approx 620$ pC/N) in lead-free $\text{Ba}(\text{Ti}_{0.8}\text{Zr}_{0.2})\text{O}_3$ - $(\text{Ba}_{0.7}\text{Ca}_{0.3})\text{TiO}_3$ system with a rhombohedral-tetragonal (r-T) phase

boundary (Zhu *et al.*, 2014). Tan *et al.* reported that Sr and Nb co-modified BNT-based ceramics deliver a superior strain value ($S = 0.7\%$) (Liu and Tan, 2016).

Piezoelectric single crystals

Relaxor based ferroelectric single crystals, such as $\text{Pb}(\text{Mg}_{1/3}\text{Nb}_{2/3})\text{O}_3\text{-PbTiO}_3$ (PMN-PT) and $\text{Pb}(\text{Zn}_{1/3}\text{Nb}_{2/3})\text{O}_3\text{-PbTiO}_3$ (PZN-PT), have attracted extensive attention over the last 20 years due to their ultra-high piezoelectric properties (Zhang and Li, 2012). The longitudinal piezoelectric strain coefficient d_{33} and electromechanical coupling factor k_{33} , being on the order of > 1500 pC/N and 0.9, far out-performs the state-of-art polycrystalline $\text{Pb}(\text{Zr,Ti})\text{O}_3$ (PZT) ceramics. The properties of relaxor-PT single crystals are summarized in Table 2. These properties are highly promising for various electromechanical applications. The piezoelectric response is highly dependent on the crystallographic orientation of the single crystals and it can be further improved by selecting MPB composition and substituting suitable elements on the desired lattice sites. Recently, Zhang *et al.* successfully explored derivative materials based upon Sm-doped $\text{Pb}(\text{Mg}_{1/3}\text{Nb}_{2/3})\text{O}_3\text{-PbTiO}_3$ (Sm-PMN-PT) single crystals having high d_{33} values in the range of 3400–4100 pC/N, with the variation below 20% over the as-grown crystal boule, which shows good property uniformity (Li *et al.*, 2019).

Textured piezoelectric ceramics

Despite the fact that single crystals have ultrahigh piezoelectric properties, as mentioned above, these materials have been facing challenges in their deployment mainly due to the high cost related to fabrication. Obtaining large size single crystals with required chemical homogeneity has been challenging. The use of single crystals is generally limited to medical imaging applications where performance considerations outweighs the materials cost. To overcome the production challenges of single crystal, textured piezoelectric ceramics with strong anisotropic properties have been developed, such as $\langle 001 \rangle$ textured PMN-PT, and $\text{Pb}(\text{Mg}_{1/3}\text{Nb}_{2/3})\text{O}_3\text{-PbZrO}_3\text{-PbTiO}_3$ (PMN-PZT) prepared by templated grain growth (TGG) method. Textured ceramics have shown significant improvement of piezoelectric property comparable to that of single crystal, but the cost is similar to that of traditional ceramics.

In order to obtain the textured ceramics, micro-sized template crystals are aligned in the ceramic matrix powders using tape casting method. During high temperature sintering, epitaxial growth occurs on the template seeds giving rise to textured grains (Messing *et al.*, 2004). The anisotropic shaped (whisker or platelet) template seeds should have smaller ($< 15\%$) lattice mismatch with the matrix phase for achieving high degree of texturing (Messing *et al.*, 2004). The anisotropic BT templates are synthesized using topochemical microcrystal conversion process (Liu *et al.*, 2007). These templates are used to fabricate various highly textured piezoelectric materials with excellent properties.

Polymer-based piezoelectric materials

Besides piezoelectric ceramics, there are piezoelectric polymer materials which have semi-crystalline structure, for example, polyvinylidene fluoride (PVDF), polyamides, ParyleneC, liquid crystal polymers, PVDF-TrFE block copolymer etc. The operational principle for these piezoelectric polymers is similar to that of piezoelectric ceramic materials. The semi-crystalline polymers have microscopic crystals inside matrix which are also polarized and function as dipoles as described Fig. 3. The microcrystals are distributed within an amorphous matrix. To obtain effective piezoelectricity in such materials, these small crystals should be reoriented and kept in one orientation through electrical poling or mechanical stretch process. The polyvinylidene fluoride (PVDF) material has been explored as an important piezoelectric polymer due to its high piezoelectric coefficient (20–53 pC/N) (Karan *et al.*, 2019, 2015). Correspondingly, its copolymers poly(vinylidene fluoride-co-hexafluoropropene) (PVDF-HFP) and PVDF-TrFE have received much greater attention in the area of piezoelectric energy harvesting (Hong *et al.*, 2012). The polymers are highly attractive in some applications due to light weight, high flexibility, long-term stability and easy processing under external electric field. Among all the phases (α , β , γ , δ) of PVDF, polar β (TTTT) and semi-polar γ (T_3GT_3 G') are highly desirable due to their piezoelectric nature. Between these electrically active polar phases, the β phase is of greater importance due to its large polarization and high piezoelectric constant (Fig. 4; Martins *et al.*, 2014).

Although the piezoelectric coefficients of PVDF are not so high as compared to inorganic piezoelectric materials, its unique flexible nature renders good processing for the preparation of fibers, wires, or films, and simple integration with functional materials for better output performances. To achieve better output performance, stabilization of the polar phase in PVDF is generally done through alignment of $-\text{CH}_2/\text{CF}_2-$ dipoles using traditional electrical poling processes. The Nylon-11 nanowire, has been found to show good piezoelectric behavior with a d_{31} of up to ≈ 15 pC N^{-1} at a relatively higher temperature (up to 200°C) (Datta *et al.*, 2017). Cui *et al.* reported that direct piezoelectric responses can be generated through rationally designed piezoelectric architectural units that can be realized via additive manufacturing of highly sensitive piezo-active lattices (Cui *et al.*, 2019). Results demonstrated that PZT polymer composite fabricated using 3D printed technique have relevance for anisotropic energy harvesting.

There is another type of piezoelectric material known as voided charged polymer (VCP, sometimes called ferroelectret or piezoelectret) that contains internal gas voids. When the polymer surfaces surrounding the void are charged by electrical poling or X-ray, the space charges are created inside matrix and the VCP behaves like piezoelectric material. These polymers have very high d_{33} values. However, these piezoelectric polymers have serious life time and aging problems. The VCP is easily neutralized in extremely moist environment and the surface charge can be rapidly decayed at high temperatures. Some common piezoelectric materials with their formulations, crystalline forms, and piezoelectric coefficients are listed in Table 2.

Fig. 4 (A) Chemical structure of PVDF and (B) schematic illustrations of chain conformation for α -, β -, and γ -phases in PVDF.

Selection of piezoelectric materials for energy harvesting

The transduction rate is the primary factor for the selection of piezoelectric materials. The magnitude of the transduction rate is governed by the product of piezoelectric strain constant (d) and the effective piezoelectric voltage constant (g). This can be understood by considering the electric energy available under an alternating stress excitation: (Priya *et al.*, 2019; Xu and Kim, 2012)

$$P = U_e = \frac{1}{2} CV^2 = \frac{1}{2} \epsilon_0 \epsilon_r \frac{A}{t} \left(-\frac{g \cdot F \cdot t}{A} \right)^2 \frac{1}{2} (d \cdot g) \left(\frac{F}{A} \right)^2 \cdot (At) \quad (7)$$

or energy density (u_e),

$$u_e = \frac{1}{2} (d \cdot g) \cdot \left(\frac{F}{A} \right)^2 \quad (8)$$

where F is the applied force, A is the area, and t the thickness of active piezoelectric material. This expression demonstrates that under given experimental conditions, a material with a higher $(d \cdot g)$ product is expected to generate higher power. Therefore, $d \cdot g = d^2 / \epsilon_0 \epsilon_r$ was proposed as a figure of merits (FOMs) of piezoelectric materials for energy harvesters (Islam and Priya, 2006). However, there is a challenge in achieving a high $d \cdot g$ coefficient via the composition modification in conventional piezoelectric ceramics because any increase in the piezoelectric constant (d) is always accompanied by the large increase in dielectric permittivity (ϵ); thus, high d usually shows lower g . Recently, it was found that the templated grain growth (TGG) technique yields textured PMN-PZT piezoelectric ceramics with large $(d \cdot g)$ magnitude, as shown in Fig. 5(A) and (B). This method provides more than ~ 5 times increase in the piezoelectric coefficient d , and a giant magnitude of $d \cdot g$ coefficient with value of $59\,000 \times 10^{-15} \text{ m}^2 \text{ N}^{-1}$, which is comparable to that of the single crystal counterpart and 359% higher than that of the best commercial compositions (Yan *et al.*, 2013). Using this TGG technique, two goals were achieved: (1) $\langle 001 \rangle$ texturing (grain orientation along the $\langle 001 \rangle$ crystallographic direction) of piezoelectric ceramic with engineered domain state to achieve high d and (2) realization of high $d \cdot g$ coefficient by suppressing ϵ of textured piezoelectric ceramic through the use of low ϵ templates.

Figure of merit for energy harvesting

Besides the basic piezoelectric properties (d and g), different figures of merits (FOMs) of piezoelectric materials have been proposed based on the consideration of device structures/configurations, working modes, and dimensions/scales. When it comes to resonance conditions, the effect of the loss and mechanical quality factor need to be considered. Oliver and Priya proposed a dimensionless figure of merit (DFOM), given as: (Bedekar *et al.*, 2010)

$$\text{DFOM} = \left(\frac{k_{31}^2 Q_m}{s_{11}^E} \right)_{\text{on-resonance}} \left(\frac{d_{31} g_{31}}{\tan \delta} \right)_{\text{off-resonance}} \quad (9)$$

where k_{31} is the transversal electromechanical coupling factor, Q_m is the mechanical quality factor, s_{11}^E is the elastic compliance at the constant electric field, d_{31} is the transversal piezoelectric strain constant, g_{31} is the transversal piezoelectric voltage constant, and $\tan \delta$ is the loss factor.

For micro-electromechanical systems (MEMS), where piezoelectric stress coefficients are typically used due to the constrained boundary conditions, an analogous FOM of $e \cdot h = e^2 / \epsilon_0 \epsilon_r$ is proposed. MEMS energy harvesters typically have a composite beam structure, which consists of a thin film of the piezoelectric material on an elastic substrate. Roundy *et al.* (2003) derived the expression for maximum power ($P_{\max}$) from the piezoelectric vibrational harvester as:

$$P_{\max} = \frac{1}{4} \left(\frac{e_{31}^2}{\epsilon_0 \epsilon_{33}^T} \right) \left(\frac{1 - \nu}{E_y} \right) \left(\frac{m}{\omega_0} \right) Q_{\text{tot}}^2 a_0^2 \quad (10)$$

where Poisson ratio ν , and Young's modulus E_y of the substrate material are considered besides the piezoelectric film itself. A method of delineating the contribution of material, composition, geometry, mechanical damping, and end mass to the power output of MEMS piezoelectric energy harvesters through scaling analysis is important as the power generated by the micro-scale harvesters scales down rapidly. The power generated by the MEMS piezoelectric harvester in terms of the force of excitation F_0 , proof mass m , natural frequency ω_n , and power factor Π is given by the ratio of $(F_0^2 \Pi)$ and $(m \omega_n)$. The power normalized by

Fig. 5 (A) Comparison of g_{33} and d_{33} values of various piezoelectric ceramics. Different colored lines (i), (ii) and (iii) indicate the plots of $g_{33} \cdot d_{33} = c$ function; (i) $c = 16,500 \times 10^{-15} \text{ m}^2 \text{ N}^{-1}$, (ii) $c = 30,000 \times 10^{-15} \text{ m}^2 \text{ N}^{-1}$ and (iii) $c = 50,000 \times 10^{-15} \text{ m}^2 \text{ N}^{-1}$; (B) Comparison of $d_{33(T)}/d_{33(R)}$ ratio vs. $d_{33(T)}$ of various textured piezoelectric ceramics. The $d_{33(T)}$ and $d_{33(R)}$ represent d_{33} of textured ceramic and that of randomly oriented counterpart respectively. BNT and KNN represent $(\text{Bi}_{1-x}\text{Na}_x)\text{TiO}_3$ and $(\text{K}_{1-x}\text{Na}_x)\text{NbO}_3$ compositions respectively.

acceleration squared is decomposed as a product of five factors, namely, scaling factor S , composition factor C , inertial factor I , material factor M , and power factor P , abbreviated as SCIMP factors. This method is successfully implemented to estimate and compare the performance of different MEMS energy harvesters (Sriramdas and Pratap, 2017).

Impedance matching

Similar to the natural frequency matching with an external vibration source, the impedance of the piezoelectric energy harvester should be matched to that of an external circuit in order to maximize the power extraction. Usually, an electrical impedance matching circuit is placed between the piezoelectric generator and external loads such as a rechargeable battery and supercapacitor. Thus, the matching network should be lossless and requires that the input impedance should be matched to the output impedance. The electrical input impedance of the piezoelectric energy harvester is described as follows: (Priya *et al.*, 2019)

$$Z = 1/\omega C_0 \quad (11)$$

where ω is vibration frequency of energy harvester, and C_0 is capacitance of piezoelectric materials. The impedance matching circuit consists of a combination of capacitors, inductors and resistors in accordance with the impedance of the piezoelectric energy harvester.

Piezoelectric nanogenerator

The idea of piezoelectric nanogenerator using ZnO nanowire has been explored by Wang *et al.* (2008), Wang and Song (2006) to provide the self-powered nanotechnology, aiming at powering nanodevices/nanosystems using the energy harvested from the environment in which the systems are supposed to operate. The working principle of PENG can be explained in two different ways: the force exerted perpendicular and parallel to the axis of the nanowire materials as shown in Fig. 6(A)–(C), Wang (2011).

The working principle for the primary case (Fig. 6(A, B)) can be clarified by a vertically developed nanowire subjected to the horizontally moving tip. During application of external force by moving tip to the piezoelectric structure it gets deformed. The piezoelectric impact will generate the electric field inside the nanostructure; the extended part with the positive strain will display the positive electrical potential, while the compressed part with the negative strain will show the negative electrical potential. This is because of the relative displacement of cations and anion in the crystalline structure. Therefore, the tip of the nanowire will have an electrical signal on its surface, while the lower part of the nanowire is neutralized since it is grounded. The maximum voltage produced in the nanowire can be determined using the following equation (Wang *et al.*, 2008).

$$V_{\max} = \pm \frac{3}{4(\kappa_0 + \kappa)} [e_{33} - 2(1 + \nu)e_{15} - 2\nu e_{31}] \frac{a^3}{l^3} v_{\max} \quad (12)$$

where κ_0 is the permittivity in vacuum, κ is the dielectric constant, e_{33} , e_{15} and e_{31} are the piezoelectric coefficients, ν is the Poisson ratio, a is the radius of the nanowire, l is the length of the nanowire and $v_{\max}$ is the maximum deflection of the nanowire's tip. The electrical contact plays an important role to pump out charges in the surface of the tip. Since the ohmic contact will neutralize the electrical field generated at the tip, the Schottky contact must be formed between the counter electrode and the tip of the nanowire. In order to form an effective Schottky contact, the electron affinity (E_a) must be smaller than the work function (ϕ) of the metal composing the counter electrode. For the second case, a model with a vertically developed nanowire stacked between the ohmic contact at its base and the Schottky contact at its top is considered. At the time of applied force toward the tip of the nanowire, the uniaxial compressive is created in the nanowire. Because of the piezoelectric impact, the tip of the nanowire will have a negative piezoelectric potential, increasing the Fermi level at the tip. Since the electrons will flow from the tip to the base through the external circuit thus, the positive electrical potential will be produced at the tip. The Schottky contact will block the electrons being

Fig. 6 The working mechanism of PENG where force is exerted perpendicular to the growing direction of nanowire. (A) An AFM tip is swept through the tip of the nanowire. (B) The nanowire is integrated with the counter electrode with AFM tip-like grating. (C) Working principle of nanogenerator where an individual nanowire is subjected to the force (F) exerted parallel to the growing direction of nanowire.

moved through the interface, hence keeping up the potential at the tip. As the force is taken out, the piezoelectric impact reduces, and the electrons will be streaming back to the top to neutralize the positive potential at the tip. In this case, an alternating current signal is generated.

Geometrical configuration

According to the configuration of piezoelectric nanostructure, most of the nanogenerators can be categorized into three types: vertical nanowire integrated nanogenerator (VNG), lateral nanowire integrated nanogenerator (LNG) and nanocomposite nanogenerators (NNG). There are few designs which do not fall into the aforementioned classes. VNG is a three dimensional design consisting of a pile of three layers (in general); base anode, vertical piezoelectric nanostructure layer, and the counter terminal. LNG is a two-dimensional arrangement comprising of three sections: the base anode, the horizontal piezoelectric nanostructure and the metal cathode for Schottky contact. In most cases, the thickness of the substrate film is much higher than the diameter of the piezoelectric nanostructure, so the individual nanostructure is exposed to the tensile strain. NNG is a three-dimensional setup comprising of three fundamental parts: the metal plate terminals, the vertical piezoelectric nanostructure and the polymer grid which fills the middle of the piezoelectric nanostructure. NNG can achieve high energy conversion effectiveness as demonstrated using unique nanogenerator designs based upon ZnO nanowires.

Fundamentals of Triboelectricity

When a given material makes contact with a dissimilar material under force, the difference in chemical potential of the two surfaces will result in a charge transfer across the interface, thereby, making surfaces of both the materials electrically charged after separation. If the electrodes are connected to external load, current will flow between them to screen out the electric field built up by the charged surfaces. As they are brought into contact again by outside mechanical stimuli, the expected potential difference on the electrodes will change and current will stream in opposite direction. A consistent AC output can be acquired by repeating this activity cycle. In other words, the device operates on the coupling of two commonly observed phenomena, contact electrification and electrostatic induction, with the former providing the static polarized charges on material surfaces and the latter driving the transformation of mechanical energy to electricity via mechanically triggered change in electric potential. The current is caused by the polarization field generated by the electrostatic charge on the surface of the dielectric material. The Maxwell's displacement

current is as follows (Wu *et al.*, 2019)

$$J_D = \frac{\partial D}{\partial t} = \varepsilon \frac{\partial E}{\partial t} + \frac{\partial P_s}{\partial t} \quad (13)$$

where, J_D is the displacement current density, D is the electric displacement vector, ε is the permittivity of the medium, E is the electric field, and P_s is the polarization field. The initial term indicates a time-varying electric field and is attached to the origin of electromagnetic waves, while the second term presents the commitment from surface polarization and is the origin of nano-generators. More specifically, in PENGs, the polarization comes from piezoelectric polarization charges generated by applied strain. -varying surface polarization as two materials in contact undergo mechanically agitated displacement. It has two electrodes connected to external load and two dielectrics for contact electrification. The surface is partially charged and the charges are non-mobile static charges, and triboelectric induced surface charge density σ_{tribo} builds up as a number of contacts between the two dielectric media and finally reaches a saturation, and it is independent of the gap distance z . The electrostatic field built by the triboelectric charges drives electrons to flow through the external load, resulting in an accumulation of free electrons in the electrode, $\pm \sigma_{\text{tr}}(z, t)$, which is a function of the gap distance $z(t)$ between the two dielectrics. The triboelectric charges build up an electrostatic field, which drives free electrons to flow through the external circuit. The corresponding displacement current can be calculated as

$$J_D = \frac{\partial D_z}{\partial t} = \frac{\partial \sigma(z, t)}{\partial t} \quad (14)$$

The displacement current is originated from the only conduction mechanism for electron transport in capacitive conduction and leads to the output current of TENG through electromagnetic waves and inductive current, rather than the direct flow of free charges across the electrodes. The current of TENG, considering the capacitive conduction model (Fig. 7(A) (ii)), is given by (Fan *et al.*, 2012)

$$I = \frac{\partial Q}{\partial t} = A \frac{\partial \sigma}{\partial t} \quad (15)$$

The mismatch of surface charge between the two electrodes of TENGs leads to the two different phenomena in the triboelectric effect. The initial part is related to the triboelectric charges that contributes to generating an output open-circuit voltage, $V_{OC}(z)$, which is a function of separation distance (z). The transferred charges (Q) contribute towards the mismatch of the fraction of electric potential. When there are no triboelectric charges, the structure behaves similar to a typical capacitor. The contribution of the transferred charges between the two electrodes is equal to $-Q/C(z)$, where C indicates the capacitance between the two electrodes. According to the electrical potential superposition principle, the total voltage between the electrodes is represented as: (Niu and Wang, 2015)

$$V = -\frac{1}{C(z)} \times Q + V_{oc}(z) \quad (16)$$

The V - Q - z relationship is the governing equation for TENGs in principle, which clearly describes its inherent capacitive nature. The separation between the materials leads to a surface charge mismatch and generates electrical potential between the two electrodes. The electrical potential promotes the current between electrodes when the external circuit is connected between the electrodes. In short-circuit (SC) conditions, the transferred charges (Q_{SC}) fully screen the electrical potential created from polarized triboelectric charges. Hence, the following equation can be derived for the short-circuit condition of the TENGs: (Niu and Wang, 2015)

$$0 = \frac{1}{C_z} Q_{sc}(z) + V_{oc}(z) \quad (17)$$

The basic fundamental relationship between Q_{SC} , C , and V_{OC} are shown by

$$Q_{SC} = C(z)V_{oc}(z) \quad (18)$$

The current transport relation of a TENG in the contact-separation mode is given as:

$$AR \frac{\partial \sigma(z, t)}{\partial t} = -\sigma(z, t)[d_1/\epsilon_1 + d_2/\epsilon_2] - H(t)[\sigma(z, t) - \sigma_T]/\epsilon_0 \quad (19)$$

where $H(t)$ indicates a function depending on the contacting rate between the two dielectrics, A indicates the electrode area, R represents the load resistance, z signifies the thickness of the film, and σ symbolizes the polarization charge density.

According to the transport relation, the displacement current, electric potential, output current, and output power can be estimated for the four basic TENG working modes. Four types of fundamental TENGs have been proposed in literature, as shown in Fig. 7. Fig. 7(B) (i) shows the vertical contact separation mode TENG, where two different dielectric film surfaces touch each other. The conducting metal films are sputtered on the bottom and top surfaces in the device. When these two different surfaces touch each other, the opposite charges are developed on both surfaces. When these two surfaces separate from each other by small gap through tiny external force, potential drop was observed. Thus, when both surface electrodes are well connected through external load, then free electrons will move from one active electrode to another to create an opposite potential in order to maintain the electrostatic field. The generated triboelectric charges will be vanished when gap is closed and electrons will flow back. The TENG generates a positive output voltage and short circuit current upon contact between the materials whereas it generates negative output voltage with negative when they are separated. The sliding or moving of the top (upper) surface on the bottom one (lower) would alter distribution of local electrical field for finite size of TENG, and thus the charged electrons on both ground and bottom electrode is exchanged to balance the potential variation of the electrode. For single electrode TENGs mode, bottom electrode part is grounded and it is used for mobile cases, since this type of TENG can move freely (Fig. 7(B) (iii)). Single electrode TENG method is operated in both ways via contact-sliding mode and contact-separation mode. If the size of the TENG is finite, an approaching or departing of the top object from the bottom one would change the local electrical field distribution, so that there are electron exchanges between the bottom electrode and the ground to maintain the potential change of the electrode. The mode can be useful for utilizing the energy from a moving object without attaching an electric connection, such as human walking, moving car, finger typing and more. For freestanding TENG mode, two symmetric electrodes are kept under a dielectric layer (Fig. 7(B) (iv)). The electrode size and gap distance among the two electrodes are of the same order as the moving object size. The movement of the moving object on the electrodes developed asymmetric charge distribution, resulting in flow of electrons among the two electrodes to adjust the local potential distribution (Fig. 7(D)) (Wang, 2015).

Parametric analysis

Charge injection depth

The triboelectric interface must have the capacitance characteristics to generate the charge in the system. The initial cause of tribological electrification depends on the presence of the internal electric fields in solid insulators. In all types of triboelectric contact modes, the charge is effective to a certain depth to form the capacitance. This depth is called the charge injection/penetration depth (λ). The capacitance characteristics in the triboelectric effect can be depicted with λ as (Pan and Zhang, 2019)

$$C = \epsilon S / 4\pi k \lambda \quad (20)$$

Fig. 8 The capacitive configuration for triboelectric interface.

where C is the equivalent capacitance, ε is the dielectric constant of material, and k is the electrostatic constant. The simplest configuration with the capacitance in the triboelectric interface is shown in Fig. 8.

This material-determined capacitance formed by the charge injection depth possibly interacts with interfacial air capacitance, which influence the dynamical responses of the triboelectric effect (air has breakdown voltage strength as stated by Paschen's law) (Sow *et al.*, 2013).

Surface charge density

The surface charge density σ is a parameter for quantifying the effective electric charges on both surfaces, and determines the efficiency of triboelectric devices. It serves as the basis for analyzing parameters such as the area power density and volume energy density. The surface charge and interface electrical performance is described, as in following equation: (Pan and Zhang, 2019)

$$V = f(Q) \cong f(A_{\text{eff}} \times \sigma) \quad (21)$$

where Q is the charge on the surface with an effective area of A . The accumulating charge will then introduce a voltage V . One critical point is that the final surface charge density significantly differs from the triggered charges led by the driving force of tribo-contacts. This is mainly because of charge backflow when the contact surfaces are dynamically moving farther or closer. This is a natural process in the capacitive configuration, as shown in Fig. 8.

Strategies for improving triboelectric charge density

Plenty of research efforts on TENG have been devoted to improve the triboelectric charge density, in terms of the output voltage, current, and power (Wu *et al.*, 2019). These endeavors are classified into three strategies: (1) modification in material composition, (2) improvement in effective contact area, and (3) change in environmental conditions (Fig. 9). The material modification strategy (Fig. 9(A)) is further divided into chemical surface functionalization and bulk composition manipulation. In chemical surface functionalization, the triboelectric material is modified by changing the functional groups exposed on the surface so that its charge capture capability is enhanced. In bulk composition manipulation, composite materials are generally fabricated by optimizing the material composition so that the charge-attracting or charge-trapping capability is enhanced. The second strategy for improving the triboelectric charge density (Fig. 9(B)) is based on improvement of effective contact area. The effective contact area between two solid materials is generally far from 100% due to surface roughness, and thus by simply improving the contact effectiveness, the total amount of triboelectric charges will increase even if the surface charge density where the contact electrification occurs remains unchanged. The third strategy is to introduce change in environmental conditions such as temperature and pressure (Fig. 9(C)).

The electrical output performance of a TENG is strongly depends on temperature which decreases with increasing temperature from -20 to 20°C , remained stable from 20 to 100°C , and dropped rapidly afterward. The temperature-dependent change in output charge density is attributed to the change in material permittivity and temperature-induced surface defects such as surface oxidation. As temperature, pressure also an important factor by which one can improve the triboelectric charge density of a TENG operating at high vacuum ($\approx 10^{-6}$ torr).

Choice of materials for triboelectric harvesters

Most of the materials such as metal, polymer, silk, and wood have triboelectric effect. However, the ability of a material for gaining/losing electron depends on its polarity. Wilcke (Gillispie, 2019) have proposed a triboelectric series based on order of polarity. A material towards the bottom of the series attain a more negative charge when touched to a material near the top of the series. The further away two materials are from each other on the series, the greater the charge transferred. Zou *et al.* (2019) introduced a standard method to quantify the triboelectric series for a wide range of polymers, establishing quantitative triboelectrification as a fundamental materials property. The triboelectric charge density (TECD) is measured with respect to a shape adaptable soft liquid metal to consider the ideal surface contact with the material at $20 \pm 1^\circ\text{C}$ temperature, 1 atm pressure and 0.43% relative humidity (RH). It is possible to achieve proper TECD by selecting proper materials for the fabrication of TENGs by contacting and separating with the liquid metal under same contact pressure. Using this series, one can choose a perfect triboelectric materials to fabricate proper TENG according to desired energy harvesting applications (Fig. 10).

Figure of merit

The proposed figure of merit (FOM) for TENG consists of a structural FOM (FOM_S) and a material FOM (FOM_M) (Zi *et al.*, 2015). Cycles for maximized energy output (CMEO) method by employing instantaneous short-circuit conditions during TENG operation facilitates that cycling charge (Q_C) is equal to maximum transferred charges ($Q_{SC,max}$). The maximized energy output per cycle (E_m) from the CMEO method can be expressed by

$$E_m = 1/2 Q_{SC,max} (V_{OC,max} + V'_{max}) \quad (22)$$

where $Q_{SC,max}$, $V_{OC,max}$, and V'_{max} are all proportional to the triboelectric charge density σ . Given that the average output power and energy-conversion efficiency at the CMEO are proportional to maximum energy output (E_m)/maximum displacement (x_{max}), a dimensionless structural FOM is proposed as

$$FOM_S = (2\varepsilon_0/\sigma^2 A) \times (E_m/x_{max}) \quad (23)$$

where ε_0 is the permittivity of vacuum and A is the triboelectrification area of TENG. The term $\sigma^2 A$ is introduced in the denominator so that the effects of material properties and device size are excluded in the FOM_S . Consequently, the performance FOM is defined as

$$FOM_P = FOM_S \times \sigma^2 = (2\varepsilon_0/\sigma^2 A) \times (E_m/x_{max}) \quad (24)$$

where σ^2 can be defined as the FOM_M . The FOM_S is dependent on the maximum displacement x_{max} and can be optimized by adjusting the value of x_{max} . The $FOM_{S,max}$ for different working modes of a TENG was proposed where free standing mode has

Fig. 10 Triboelectric series of materials and their triboelectric charge density. Reproduced with permission Zou, H., Zhang, Y., Guo, L., *et al.*, 2019. Nature Communications 10, 1–9. Copyright 2019, Springer Nature.

maximum FOM and single contact mode has minimum FOM (contact freestanding triboelectric-layer mode > contact-separation mode > sliding freestanding triboelectric-layer mode > lateral-sliding mode > single-electrode contact mode).

A standard method for quantifying the triboelectric performance of a material is proposed as well. The triboelectric charge density of the test material with respect to a certain liquid metal such as Galinstan is measured. A dimensionless material FOM is defined by normalizing the triboelectric charge density from the test material with that from a reference material such as fluorinated ethylene propylene (FEP)

$$\text{FOM}_{\text{DM}} = (\sigma_N)^2 = \sigma_{\text{Material/Galinstan}}^2 / \sigma_{\text{FEP/Galinstan}}^2 \quad (25)$$

The use of liquid metal rather than solid materials is justified by the more intimate contact of a liquid–solid interface and thus less influence of surface roughness. A negative σ_N means the material is more triboelectrically positive than Galinstan, and a σ_N larger than one means it is more triboelectrically negative than FEP, and something in between means it is more negative than Galinstan but more positive than FEP.

Fundamentals of Magneto-Mechano-Electric (MME) Effect

MME generators are capable of harvesting energy from both mechanical vibrations and alternating magnetic fields because both the piezoelectric and magnetoelectric effects are present in an MME generator. The magneto-mechano-electric (MME) generators consisting of a magnetic mass on a cantilever beam structure have been promising to harvest the energy in magnetic fields through the magnetoelectric (ME) effect. However, the performance of MME generators has been enhanced by employing magnetostriction resulting in strain mediated magnetoelectric effect in the MME generators. The structure of an ME coupled MME generator is similar to that of an MME generator with the elastic layer replaced by a magnetostrictive material. In addition to the end magnetic torque, the force due to the magnetostriction further enhances the strain in the piezoelectric layer, thus increasing the power generation capability. Thus both the piezomagnetic coupling constants in magnetostrictive material and piezoelectric coupling constants in piezoelectric material simultaneously contribute to the enhancement in the power levels in magnetic field harvesters (Ryu *et al.*, 2015). MME generators are capable of harvesting energy from both mechanical vibrations and alternating magnetic fields because both the piezoelectric and magnetoelectric effects are present in an MME generator (Ryu *et al.*, 2015). To enhance the efficiency and power output of ME energy harvesters, the combination of these two techniques through MME generators is considered to be a good strategy. A dual-phase (vibration and magnetic) MME generator combines the ME coupling and piezoelectric energy harvesting mechanisms, as shown in Fig. 11. In the case of dual-phase harvester, the MME generator is simultaneously excited by an AC magnetic field (H_{ac}) generated by stray magnetic fields and ambient mechanical vibrations. In an MME generator, the AC magnetic field is converted into an electric field in two steps. In the first step, the oscillating magnetic field is converted into mechanical vibration through the magnetostriction of the magnetostrictive layer and the torque generated by a permanent magnet. In the next step, mechanical strain due to the vibration is converted into the electric field through piezoelectric material. The torque acting on a magnet of volume V , and surface S placed in a magnetic field with flux density B_{ext} is given as: (Furlani, 2001)

$$T = \int_V r \times (J_m \times B_{\text{ext}}) dv + \oint_S r \times (j_m \times B_{\text{ext}}) ds \quad (26)$$

where J_m and j_m are equivalent volume and surface current densities, respectively, and r is the vector of interest for torque computation. The force due to the torque on the beam is dependent on the beam's shape function, ϕ , in the respective mode shape and hence, the location and geometry of the magnet affect the force of excitation. The force from a permanent magnet as a function of time t , on the beam with length L , and a magnet with width w and projected area A , when placed in an external field intensity $H_1(t)$ is given by (Sriramdas *et al.*, 2020)

Fig. 11 The working principle and the energy transfer processes in an MME energy harvesting device. Reproduced with permission from Ryu, J., Kang, J.-E., Zhou, Y., *et al.*, 2015. *Energy & Environmental Science* 8, 2402–2408. Copyright 2014, Royal Society of Chemistry.

$$F_1 = wAB_r H_1(t) \phi(L) \quad (27)$$

where B_r is the remanent flux density of the magnet. However, the force offered by the magnetostriction in a cantilever beam is derived from the force and moment balance on an infinitesimal element of the beam using Newton's second law or Hamilton's principle (Meirovitch, 2010). The thickness of the magnetostrictive layer, t_m , elastic modulus c_{11m} and width b , and the magnetostrictive strain coupling constant d_{31m} directly increase the force of excitation due to the magnetostriction. Using the height of the neutral layer Z , the magnetostrictive force of excitation is given by

$$F_2 = c_{11m} d_{31m} b t_m \left(\frac{t_m}{2} - \bar{z} \right) \phi'(L) H_1(t) \quad (28)$$

The electromechanical coupling coefficient (Sriramdas et al., 2015) G , for the MME harvester, depends on the piezoelectric stress constant e_{31} , and the layer thickness t_p along with the magnetostrictive and adhesive layers t_m and t_a . The piezoelectric coupling coefficient G for the two-layer MME is given by,

$$G = e_{31} b \left(t_m + t_a + \frac{t_p}{2} - \bar{z} \right) \phi'_2(x)|_{x=L} \quad (29)$$

Multiple magnetostrictive layers are often used in designing MME harvesters to obtain large magnetostriction while maintaining a low frequency of resonance for the beam (Kang et al., 2018). The force of excitation due to the magnetostriction of the composite beam with piezomagnetic stress constant e_{31m} in the i^{th} layer of the magnetostrictive layer is given by

$$F_2 = b \sum_{i=1}^{2n-1} e_{31mi} t_i \left(\sum_{j=1}^{i-1} t_j + \frac{t_i}{2} - \bar{z} \right) \phi'(x)|_{x=L} H_1(t) \quad (30)$$

The forces F_1 and F_2 act simultaneously on the beam when ambient stray magnetic fields are present. These forces cause the beam to deform, thereby causing strain in the piezoelectric material. The cyclic change in the strain, results in a flow of charge from the piezoelectric material terminals when connected to an external load resistance. The MME composite transduction is a promising method of scavenging energy from magnetic fields owing to the strong ME coupling between the magnetostrictive and piezoelectric layers (Ryu et al., 2001).

Types of ME transducers

The magnetoelectric coupling effect in magnetostrictive-piezoelectric layered composites depends on the type of MME. The MME can be broadly classified into two groups of configurations (1) asymmetric transducer and (2) symmetric ME transducer. An example of an asymmetric ME transducer is a bilayer structure consisting of one magnetostrictive and one piezoelectric layer. Multiple layers of single or different magnetostrictive materials combined with one piezoelectric layer can also be described as an asymmetric ME configuration. A symmetric ME transducer consists of an even distribution of magnetostrictive (M) or piezoelectric (P) materials placed symmetrically about the neutral axis of the composite. The symmetric transducer has two distributions – MPM and PMP configurations. The symmetric transducer has significant coupling in the longitudinal vibration modes of the composite, however, the asymmetric transducer responds to the magnetic fields through the bending vibration. In both transducers, the composite responds to the magnetic field in either longitudinal or transverse direction in the respective vibration mode.

Figure of merit

The ME effect induces a magnetization M_i due to an applied electric field E_j or vice versa producing an electric polarization P_i due to an applied magnetic field H_j that can be described as follows:

$$P_i = \alpha_{ij} H_j \quad (31)$$

$$M_i = \frac{\alpha_{ji}}{\mu_0} E_j \quad (32)$$

where μ_0 is the permeability of free space and α_{ij} is the ME susceptibility tensor (Bichurin and Petrov, 2014). The tensor is a second rank tensor describing the interaction between the magnetic and electric vectors, and hence, serves as a figure of merit for ME transduction. When both electric and magnetic fields are applied to the transducer, the constitutive equations describing the coupling between the electrical and magnetic layers is described using (Bichurin et al., 2002)

$$S_i = s_{ij} T_j + d_{ik} E_k + q_{ki} H_k \quad (33)$$

$$D_k = d_{ki} T_i + \varepsilon_{kn} E_n + \alpha_{kn} H_n \quad (34)$$

$$B_k = q_{ki} T_i + \alpha_{kn} E_n + \mu_{kn} H_n \quad (35)$$

where S_i , T_j , E_k , H_k , D_k and B_k are the components of strain tensor, stress tensor, electric field, magnetic field, electric displacement, and magnetic flux density vectors. s_{ij} , d_{ki} , q_{ki} , ε_{kn} , and μ_{kn} denote the effective compliance, piezoelectric, piezomagnetic, permittivity, permeability components. The ME susceptibility tensor, α_{kn} , consists of a significant term depicted by ME voltage coefficient, α_E , depending on the type of ME transducer selected. The interface between piezoelectric and magnetostrictive layers can be represented by an interfacial coupling parameter k . The ratio of volume of piezoelectric material (p_v) to the total volume of the transducer ($p_v + m_v$) is another variable denoted by volume fraction v that is used in the optimization of α_E , where v_m is the volume of the magnetostrictive phase in the transducer. The ME susceptibility or ME voltage coefficient for a bilayer longitudinal

transducer, which has both electric and magnetic fields along direction 3 normal to the plane, is denoted by $\alpha_{E,33}$. Assuming a perfect interfacial coupling ($k = 1$), the expression for $\alpha_{E,33}$ as a function of the material properties in the respective domains denoted by a prefix m for magnetostrictive layer and p for piezoelectric layer is (Harshe *et al.*, 1993)

$$\alpha_{E,33} = \frac{-2\nu(\nu - 1)^p d_{13}^m q_{31}}{(m s_{11} + m s_{12})^p e_{33} \nu + (p s_{11} + p s_{12})^p e_{33} (1 - \nu) - 2^p d_{13}^2 (1 - \nu)} \quad (36)$$

The transverse ME coupling is observed in a bilayer transducer when the direction of the magnetic field is along the longitudinal axis (direction-1) while the electric field is along direction 3. An expression for the transverse ME voltage coefficient derived by Bichurin *et al.* (2002) considering the interfacial coupling condition k is

$$\alpha_{E,31} = \frac{-k\nu(1 - \nu)^p d_{31} (m q_{11} + m q_{21})}{(m s_{11} + m s_{12})^p e_{33} k\nu + (p s_{11} + p s_{12})^p e_{33} (1 - \nu) - 2k^p d_{13}^2 (1 - \nu)} \quad (37)$$

It may be noted that when the interfacial coupling is perfect, a similar expression is reported by Filippov *et al.* (2014). A nonlinear constitutive model for Terfenol-D magnetostrictive rods can be found in Ref. Zheng and Liu (2005) by Zheng *et al.* The effect of a bias field on the ME voltage coefficient can be described by considering the nonlinear constitutive model for the magnetostrictive material. The reader is referred to Ref. Xu *et al.* (2018), Chang and Carman (2008), Bichurin *et al.* (2017) for a more detailed discussion on the figure of merit for trilayer, multilayer and graded magnetoelectric composites.

Energy Harvesting Technologies

The current portable and wearable technology heavily relies on rechargeable batteries. But for the near future, micro/nano-systems will be widely used in health monitoring, infrastructure and environmental monitoring, internet of things and defense technologies; the traditional batteries may not meet or may not be the choice as power sources for the following reasons. First, with the increasingly miniaturized devices, the size of the total micro/nano-systems could be largely dominated by the size of the battery rather than the device itself. Second, the number and density of micro/nano-systems to be used for sensor networks could be large, thus, replacing batteries for these mobile devices is challenging and even impractical. Lastly, the power needed to drive a micro/nano-system is rather small, in the range of micro- to milli-watt range. Energy harvesting is central for powering sensors without batteries. The most promising harvesting technologies that enable powering sensors from the unused ambient energy include piezoelectric energy harvesting in the form of both cantilevers and nanogenerators, triboelectric nanogenerators, and magneto-mechano-electric generators.

Cantilever Based Piezoelectric Energy Harvester

The piezoelectric energy harvesters in the form of a cantilever are preeminent in converting mechanical energy into electrical energy. The principle of generating electrical energy from the ambient motion can be explained through the energy flow associated with the transduction process. The energy transduction is maximum at the fundamental resonance of the cantilever structure. The ambient vibration energy is transferred into the structure through the base excitation. The proof mass exchanges the kinetic energy with the potential energy stored in the beam (Hajati and Kim, 2011). At steady state the amount of energy supplied to the structure reflects the energy absorbed by the system in the form of dissipation. When a piezoelectric layer is deposited on the cantilever beam, a portion of the dissipation energy is converted into electrical energy and the remaining energy is lost in the form of mechanical dissipation. A cantilever harvester designed for a specific vibrating source has its resonance frequency tuned to match the frequency of the vibrating structure. The cantilever structure parameters such as the equivalent mass, stiffness and damping have to be evaluated to tune the resonance frequency for effective transfer of energy from the vibration source. An iterative technique for obtaining these optimal parameters at which significant energy supplied to the system is transferred to the harvesters entails the determination of bandwidth of energy absorption, and dissipation energy (Sriramdas *et al.*, 2016). The resulting frequency ratio and absorber damping ratio ensure that not only the input energy is minimum but also much of the input energy is absorbed by the harvesters. The harvester is designed with the derived optimal equivalent mass, stiffness and the damping for effective absorption of energy from the vibration source. The piezoelectric cantilever harvesters are typically designed in the form of a unimorph or a bimorph (Renaud *et al.*, 2008). In contrast to a unimorph that has a single layer of piezoelectric material, a bimorph consists of two layers of the piezoelectric material distributed either in series or parallel depending on the direction of polarization.

The basic structure of the bimorph and unimorph is shown in Fig. 12. It may be noted that the bimorph shown in Fig. 12(A) has both the piezoelectric layers connected in parallel owing to the opposing stresses during bending. When the poling direction is reversed, the two terminals have to be connected in series. A unimorph on the other hand consists of a single layer as shown in Fig. 12(B).

Performance enhancements are demonstrated using multilayer and multistep harvester configurations (Sriramdas *et al.*, 2015) consisting of several layers of piezoelectric layers. Small size energy harvesters, particularly, MEMS-scale harvesters generally consist of unimorph configuration owing to the fabrication feasibility. An end mass is etched to act as a proof mass to adjust the resonance frequency typically less than 100 Hz (Reilly *et al.*, 2009). Several parameters such as electromechanical coupling coefficient, G ,

Fig. 12 (A) Bimorph structure of the piezoelectric energy harvester. (B) A unimorph configuration of the harvester with a single layer of the piezoelectric material. beam stiffness, K , equivalent mass, M , damping coefficient, C , frequency of operation, ω_n , and force of excitation, F , affect the performance of the piezoelectric unimorph harvester. The differential equations governing the output from a cantilever harvester in terms of the voltage, V , and end displacement W , are

$$M\ddot{W} + C\dot{W} + KW - GV = F \quad (38)$$

$$RC_p\dot{V} + RV + V = 0 \quad (39)$$

where C_p and R are the capacitance of the harvester and the load resistance. The power from the harvester at resonance is estimated by solving the above equations for voltage and displacement and using $P = V_{rms}^2/R$. The power is optimized with respect to the load resistance R to determine the optimum harvester impedance as

$$R_{opt} = \frac{1}{C_p\omega_n} \left[\frac{2\zeta}{\sqrt{k_e^4 + 4\zeta^2}} \right] \quad (40)$$

where k_e is the coupling factor defined as $G/(\omega_n\sqrt{MC_p})$. The power developed by the piezoelectric harvester at the optimum load resistance is given by

$$P = \frac{F^2}{M\omega_n} \left(\frac{k_e^2}{8\zeta\gamma} \right) = \frac{F^2}{M\omega_n} \Pi \quad (41)$$

where $\gamma = k_e^2 + \sqrt{k_e^4 + 4\zeta^2}$. It may be noted in the expression for power that the term inside the bracket is a nondimensional quantity, called power factor, Π (Sriramdas and Pratap, 2017). The dimensionless term indicates that the power is greater when the damping ratio is small and the coupling factor is high. A relation between the damping ratio and coupling factor that maximizes the power factor is $k_e^* = 2.258 \zeta^{0.516}$. When the coupling factor and the damping ratio satisfy this relation, the power factor simplifies to $\Pi \approx \frac{1}{16\zeta}$. It may be noted that the resulting expression for power at the optimum power factor is similar to that derived in Ref. Xu (2012) when electrical and mechanical damping are equal. In order to determine the effect of geometry, inertial mass, and material properties, the expression for power is normalized with square of acceleration and the resulting terms are represented as a product of five factors namely Scaling, Composition, Inertial, Material and Power factors (SCIMP factors) (Sriramdas and Pratap, 2017). For example, the scaling factor is the product of width and cube of length. Hence, the power from a cantilever unimorph is proportional to the width and cube of length. Similarly, the other factors are used to maximize the power from the piezoelectric cantilever harvester. The optimal resistance R_{opt} is also similar to that given in the impedance matching section when the term in square brackets converges to unity for small values of coupling factor. Hence, matching the optimum load resistance is as crucial as other performance parameters to achieve the maximum power from the cantilever based piezoelectric harvesters. Aktakka *et al.* (2011) have demonstrated large acceleration (square) normalized power of $91 \mu\text{W}/\text{g}^2$ by using a thinned PZT wafer. The resonance frequency of the harvester is 154 Hz and the power generated was close to $205 \mu\text{W}$ at 1.5 g base acceleration. Thinning down PZT wafer to MEMS scale has shown promising results in another work by Janphuang *et al.* (2014). Although the power generated is small $\sim 1.6 \mu\text{W}$, the normalized power is over $160 \mu\text{W}/\text{g}^2$ at 99 Hz resonance frequency. Similar normalized power levels of $128 \mu\text{W}/\text{g}^2$ were achieved using AlN as the active piezoelectric material in the work by Andosca *et al.* (2012). It is observed that scaling and inertial factors play a significant role in microscale energy harvesters. Kuo *et al.* (2016) conducted research on transforming vibrational energy into electrical energy using a cantilever beam structure fabricated by laminating two PZT thick-film layers on both sides of a stainless-steel substrate. At 0.5 g base excitation acceleration level, generators poled for serial and parallel connections generated open-circuit output voltages (peak-to-peak) of 11.6 and 20.1 V, respectively. Under an externally applied base excitation acceleration of 1.5 g, the generator poled for parallel connection reached a maximum output voltage of 15.2 V and an output power of $423 \mu\text{W}$ at an excitation frequency of 143.4 Hz, whereas the generator

poled for serial connection achieved a maximum output voltage of 33.0 V and an output power of 413 μW at an excitation frequency of 140.8 Hz.

Piezoelectric Nanogenerator

ZnO based PENGs

The development of nanomaterials and nanotechnology led to the demonstration of the piezoelectric nanogenerator (PENG) using zinc oxide (ZnO) nanowires. Zhu *et al.* (2010) designed a flexible PENG based on lateral ZnO nanowires which are transferred to a receiving substrate to form horizontally aligned arrays. The vertically aligned ZnO NWs on Si substrates have been synthesized using physical vapor deposition method. The dense and uniform NWs have the length of $\sim 50\text{ }\mu\text{m}$, diameter of $\sim 200\text{ nm}$, and growth direction along the *c*-axis as shown in Fig. 13(A) (i). The nanogenerator can generate an open circuit output voltage to 2.03 V and short circuit current of 107 nA (Fig. 13(A) (ii)) with a peak output power density of $\sim 11\text{ mW/cm}^3$ under external mechanical force. The generated electric energy was effectively stored by utilizing capacitors, and it is successfully used to light up a light-emitting diode (LED) (Fig. 13(A) (iii)). Furthermore, by optimizing the density of the NWs on the substrate and with the use of multilayer integration, a peak output power density of $\sim 0.44\text{ mW/cm}^2$ and volume density of 1.1 W/cm^3 were predicted. Qiu *et al.* (2012) explored a cost-effective way to harvest low-frequency mechanical energy into electric power using ZnO nanorods developed on a paper substrate using low-temperature hydrothermal method (Fig. 13(B) (i)). For the fabrication, small drops of silver (Ag) paste were separately deposited on the two ends of the ZnO–paper sample to act as the electrodes. Typically, the flexible PENGs have an effective area of 0.32 cm^2 ($0.4\text{ cm} \times 0.8\text{ cm}$) and an electrode interval of 0.4 cm . One can control the electric output signal by scaling the size of the PENG device. A schematic diagram of the setup for measuring output performance is shown in Fig. 13(B) (ii). The PENG can generate an output voltage of $\sim 10\text{ mV}$ and a current of $\sim 10\text{ nA}$, which are sufficient to power up small nanoscale electronics devices (Fig. 13(B) (iii)). The measurement has been performed at a strain of 0.1% and strain rate of $5\%\text{ s}^{-1}$ with the deformation frequency of 0.33 Hz .

Ceramic based PENGs

The PZT material is of great interest in the scientific community for the energy harvesting due to its outstanding piezoelectric properties. Kwon *et al.* (2012) reported a practical approach for realizing high-performance PZT based flexible and semi-transparent PENG (Fig. 14(A)), where graphene acts as the electrode. The fabrication of PZT ribbon-based NGs on a PET film has been demonstrated in Fig. 14(A) (i). The PZT/Pt/Ti/SiO₂ ribbons with the desired size of 500 μm × 100 μm were created using the conventional photolithographic method. The fabricated device generated an output voltage of ~2 V, current density of ~2.2 μA cm⁻², (Fig. 14(A) (ii,iii)) resulting in a power density of ~88 mW/cm³ under an applied force of 0.9 kg f. They also have explored the change in voltage and current outputs with respect to time, by continuously increasing the compressive force in three steps, as shown in Fig. 14(A) (iv, v). Hwang *et al.* (2016) demonstrated a high-performance flexible piezoelectric energy harvester, fabricated a PZT thick film on a plastic substrate using an aerosol deposition (AD) method. Fig. 14(B) (i, ii) displays the harvester model and calculated electric potential distribution of the PZT thick film with interdigitated electrode (IDE). The flexible harvester induced an open-circuit voltage of 75 V and a short-circuit current of 14 μA due to biomechanical bending motion (Fig. 14(B) (iii, iv, v)). Moreover, the maximum output voltage of 200 V and output current of 35 μA were generated by a human finger bending motion. Qi *et al.* (2011) used a transfer printing method in which, the PENG (1 cm²) was found to generate a voltage and current output of 0.25 V and 40 nA, respectively. To increase the amplitude of strain, they further developed a stretchable PENG using integration of wavy/buckled PZT ribbons with PDMS thin film. The film can be stretched up to 8% strain and enabled its integration with a flexible structure. An output current of 60 pA was generated from the device when ten PZT ribbons were assembled all together.

Cui *et al.* (2019) reported PZT nanoparticle-based composite materials and fabricated a PENG device, which generated voltages along different angles (75°, 90° and 120°) under external applied stress. The voltage output reached up to 60 mV in the case of 75° angle. The real-time voltage output of the fabricated device was measured using different free-falling weights and reached up to 2.5 V for 100 g weight, indicating the high sensitivity of the device. The PZT based implantable energy harvesting devices powered by ultrasound is an alternative way for converting acoustic energy into electricity. A piezoelectric ultrasonic energy harvester (PUEH) based on microfabricated PZT (size of 5 mm × 5 mm) has been explored by Shi *et al.* (2016) The PUEH can generate an output power density of 0.59 μW cm⁻² to 3.75 μW cm⁻² at 1 cm distance from the ultrasound source when changing the frequency

from 250 kHz to 240 kHz of ultrasound with 1 mW/cm² intensity. The device has shown a great potential in implantable medical device applications.

The ceramic material BaTiO₃ has also received attention due to its outstanding ferroelectric properties and biocompatible characteristics, which are crucial for biomedical applications. Park *et al.* (2012) designed a nanocomposite based PENG by mixing BaTiO₃ nanoparticles and carbon nanomaterials in PDMS. They have fabricated PENG based on BaTiO₃ nanoparticles (NPs) synthesized via a hydrothermal reaction and graphitic carbons, such as single-walled and multi-walled carbon nanotubes (SW/MW-CNTs), and reduced graphene oxide (RGO) as shown in Fig. 15(A) (i). The BaTiO₃ NPs and carbon nanomaterials are dispersed in polydimethylsiloxane (PDMS) by mechanical agitation to produce a piezoelectric nanocomposite. The measured output performance of nanocomposite PENG under periodic bending and unbending motions reached up to 3 V output voltage and 270 nA current respectively, as shown in Fig. 15(A) (ii). To exclude any artifact from the external electrostatic charges, the sample was placed in a Faraday cage on an optical table and bending system is well grounded. Under the continual bending and unbending cycles, the PENG device repeatedly generates an open-circuit voltage of ~3.2 V and a short-circuit current signal of 250–350 nA; these output values are produced for a maximum horizontal displacement of 5 mm from an original 4 cm long sample at a deformation rate of 0.2 m s⁻¹. The amplitude of the output voltage generated from the PENG device increases from 0.2 V to 3.2 V after the poling process and also depends on the composition of nanomaterials, the angular bending strain, and strain rate.

A bio-inspired flexible PENG has been demonstrated using BaTiO₃ (Jeong *et al.*, 2013), where metal ion precursors, and self-assembled anisotropic BaTiO₃ nanocrystals were deposited on a viral template (Fig. 15(B) (i)). The stirred and infiltrated virus-templated BTO nanostructures are mixed with polydimethylsiloxane (PDMS) to achieve the BTO piezoelectric layer (Fig. 15(B) (i)). The indium tin oxide (ITO)-coated thick (~175 μm) polyethylene terephthalate (PET) substrate is covered with PDMS dielectric layer to prevent the electric breakdown of device. Fig. 15(B) (ii) shows the photograph of fabricated virus-templated BTO nanogenerator, which is malleable and flexible indicating that nanostructure of one-dimensional fibrous materials can be well distributed in three-dimensional active regions. The fabricated PENG device with an effective area of 2.5 × 2.5 cm² generated an output voltage

and current on the order of ≈ 6 V and ≈ 300 nA under both forward and reverse connections with measurement equipment without additional structural stabilizers, indicating that the high output is related to the nanoscale structure. The Fig. 15(B) (vii) depicts the general mechanism of energy conversion by the PENG device.

Kim *et al.* (2014) developed a “layer-by-layer” method to synthesize BaTiO₃ nanoparticles based piezoelectric thin film. The composite made by oleic acid ligands stabilized BaTiO₃ nanoparticles (NP) (> 20 nm in diameter) and polymers that were functionalized by poly(acrylic acid) (PAA). The high affinity between the $-\text{COOH}$ groups and BaTiO₃ NPs assisted the organization of the nanocomposite. The performance of these piezoelectric films was found to be precisely controlled by altering the bilayer number, nanoparticle size or inserted polymer type. As the bilayer number (n) was increased from 20 to 100, the fabricated unpoled PENG device generates the output voltage and current increased to approximately from ~ 0.1 V to ~ 1.8 V and ~ 15 nA to ~ 700 nA, respectively, under a compressive force 5.2 kg f. The influence of compressive forces on the piezoelectric performance has also been verified by measuring the output voltage and current of a device containing 100 bilayers. As the compressive force was increased from 0.8 to 5.2 kg f, the output voltage and current increased from approximately ~ 0.4 V and ~ 60 nA to ~ 1.8 V and ~ 700 nA, respectively. The results demonstrate that a degree of external compressive force can significantly affect the aligned electric dipoles and the resultant piezoelectric performance of (PAA/OA-BTONP) n multilayers without an additional poling process.

Polymer-based PENGs

PVDF and its copolymer P(VDF-TrFE) are polymeric piezoelectric material with a high piezoelectric coefficient ($d_{33} = 32.5$ pC/N) (Karan *et al.*, 2019). Sun *et al.* (2011) proposed a method for converting energy from low-speed airflow to electricity using resonant oscillation of PVDF micro-belts (Fig. 16(A)). They reduced the commercial β -phase PVDF using reactive ion etching (RIE)

technique (Plasma-Therm 790, 250 W operation power). After reducing the thickness of PVDF from 26 to 11 μ m the β -phase is well-preserved without any change. For the fabrication of the device, 17 μ m thick PVDF belt was selected due to the best performance under air flow $< 2 \text{ m s}^{-1}$. For the evaluation of the device, belt was fixed at the center of a cylindrical channel with a cross-sectional area of $\sim 1 \text{ cm}^2$. One end of the channel was connected to a compressible plastic chamber that simulated the function of a lung and the other end was open (Fig. 16(A) (i)). The plastic chamber was squeezed and released every 6 s producing air flow in and out through the tunnel with a peak rate of $\sim 2.3 \text{ ms}^{-1}$ (Fig. 16(A) (ii)) and the operation provided a close simulation of typical adult's respiration. The output voltages were clearly correlated to the instantaneous flow rate and peak voltage output of ~ 0.4 – 0.5 V was detected at the highest "exhalation" flow rate of $\sim 0.5 \text{ l s}^{-1}$ (Fig. 16(A) (iii)). Due to the asymmetry of the air flow profile between inhalation and exhalation, lower output voltage was observed during inhalation cycles. The device can charge a capacitor up to $\sim 200 \text{ mV}$, after 12 min of simulated respiration, corresponding to $20 \mu\text{J}$ of electrical energy storage indicating the capability for energy harvesting through inhalation and exhalation processes.

Lin *et al.* have explored a direct-write technique utilizing near-field electrospinning to produce and place piezoelectric PVDF nanofibers on working substrates with in-situ mechanical stretching and electrical poling (Chang *et al.*, 2010). The typical electrical output of more than 50 tested nanogenerators were 5 – 30 mV and 0.5 – 3 nA. The fabricated device generated excellent output performance with good energy conversion efficiency (12.8%). Rogers *et al.* have fabricated electrospun PVDF-TrFe based self-powered PENG device for robots and sensitive impact detectors (Persano *et al.*, 2013). The device was formed simply by establishing electrical contacts to the ends of a ribbon-shaped sample of fiber arrays on a flexible polyimide (PI) support (Kapton; optimum thickness between 75 and 225 μ m), and generated large response to even minute applied pressures (Fig. 16(B) (i)). To evaluate the sensitivity quantitatively, a soft elastomer (PDMS posts) delivered well-defined levels of pressure to the arrays, while the electrical response was measured. Fig. 16(B) (iii) describes a linear variation of the output voltage with pressure. The effective contact areas between 9 and 36 mm² (squares with sides L_{eff} , Figure B(ii), with slopes between 0.41 and 0.79 mV Pa⁻¹). The devices can achieve the sensitivity of 1.1 V kPa⁻¹ in the ranges of pressure between 0.4 and 2 kPa. The devices are very sensitive to the level of response enabling accurate measurement of compressive pressures even at 0.1 Pa (Fig. 16(B) (iv)). The voltage is independent of the total length $L_{\text{PVDF-TrFe}}$ (Fig. 16(B) (v)) of the P(VDF-TrFe) fiber arrays, which is also consistent with experimental results of Fig. 16(B) (iii).

They have also fabricated the devices for measuring vibration/acceleration and orientation. The measured output voltage signal with a peak-to-peak output voltage that increases from 6 to 14 μ V generated under environmental sound pressure levels of 60–80 dB. These devices work in any orientation and can be mounted on any surface by means of transparent, skin-conformal plastic sheets. They have proved that the device can work in any orientation and can be mounted on any surface by means of transparent, skin-conformal plastic sheets. The results suggest utility in a variety of sensor- and energy harvesting components, with lightweight construction, attractive mechanical properties and potential for implementation over large areas at low cost, with application opportunities in human motion monitoring and robotics. The output performance of different small scale PENG devices is summarized in Table 3.

Triboelectric Nanogenerator

Solid-solid contact based TENGs

The TENGs harvest electrical energy from both solid–solid and liquid–solid contact. Due to their physical difference, triboelectric materials for solid–solid TENG need to have high mechanical stability for long life span and the surface of the liquid–solid contact TENG should repel water for constant liquid separation. The solid-solid contact based TENG is the common mechanism in triboelectric energy harvesting community where one solid surface contacts with another solid surface for power realization (Choi *et al.*, 2020).

A self-powered solid-solid contact based triboelectric auditory sensor (TAS) is proposed for social robotics and hearing aids by Guo *et al.* (2018). The multilayer TAS consisted of an Au-coated FEP film attached on an acrylic substrate, a spacer, and an Au-coated Kapton membrane (Fig. 17(A) (i)). The FEP-covered acrylic substrate has hole channels to reduce air damping and the Kapton membrane was fixed on the outer rim by using an annular acrylic sheet. Membrane deformation caused by acoustic waves triggers the contact and

separation between FEP and the membrane electrode, resulting in generating electrical outputs. The fabricated TAS device achieved an ultrahigh sensitivity of 112.4 mV dB^{-1} , which can be used for various applications such as a sound-controllable switch and an antitheft system. As shown in Fig. 17(A) (ii), a multiresonant frequency band was achieved by a TAS with four sectorial architectures, and this feature of broadband frequency response enables it to have applications in an electronic auditory system with high quality and fidelity in sound recording. Therefore, it can also be used in security systems using voice recognition. As in Fig. 17(A) (iii), the electrical signals from two different persons saying the same word “Hello” were recorded by the TAS device, and the results of power spectral density estimation (PSDE) and joint time-frequency analysis (JTFA) showed distinctive differences between the users. Fig. 17(A) (iv) shows the sound waves and corresponding acoustic spectrograms of original voices, weakened voices (-30 dB in the $207\text{--}837$ and $1594\text{--}2090\text{ Hz}$ frequency regions) played by a loudspeaker, and recorded voices by a TAS-based hearing aid system, which clearly indicates that the sound information in the impaired frequency regions was restored.

A solid-solid contact based TENG device of capsule-type has been introduced as an effective high-performance sensor by Wu *et al.* (2018). The TENG consisted of polyvinyl chloride (PVC) tube with an inner Al slider and outer PVC surface coated with Al electrodes (Fig. 17(B)). The diameter for the Al slider is smaller than that of the PVC tube for the free access inside the PVC tube, which makes it potentially more fitting for smart electronics. The maximum output is obtained when the length of the aluminum electrode is 10 mm as shown in Fig. 17(B) (iv). The electrical output of the capsule TENG can be further improved by introducing additional static charges to the Al slider. The additional static charges were introduced to the Al slider by shaking it in a polyvinylidene fluoride (PVDF) jug before sealing it in a capsule (inset of Fig. 17(B) (ii)). The short-circuit current of the capsule TENG is tested without preprocessing (0 s), as shown in Fig. 17(B) (ii). All of the static surface charges on the Al slider are generated due to the triboelectrification between the Al slider and the PVC tube because PVDF has a stronger ability to attract electrons than PVC. The peak current is seen to approach a saturation value of about $5.0 \mu\text{A}$ with increasing preprocessing time to 120 s. The output power from the capsule TENG under a vibration frequency of 5.0 Hz reached a maximum peak power of $2.6 \mu\text{W}$ at a load resistance of $7.5 \text{ M}\Omega$ (Fig. 17(B) (iii)). The highest electrical energy at a vibrational frequency of 5.0 Hz reached to 165 nJ during the periodic vibration (Fig. 17(B) (iv)). Recently, Choi *et al.* demonstrated an ordered dipole alignment in α -phase nylon-11 nanowires that can be used for the triboelectric energy harvesting. They have explored dipole alignment of non-ferroelectric polymer as-fabricated nanowires of α -phase nylon-11 (Choi *et al.*, 2020).

TENG can also be implanted inside a live animal for powering biomedical devices utilizing ambient available energies; they are termed implantable triboelectric nanogenerators (iTENGs). To power up body-implanted devices with TENGs, either bio-mechanical energy (from various types of muscular movements) or ultrasound energy transferred into the body are excellent mechanical energy sources that can generate electricity. These nanogenerators are a recent invention of modern energy harvesting and storage technologies which energize small in-vivo medical devices. Zheng *et al.* (2016a) used nanostructured polytetrafluoroethylene (n-PTFE, $50 \mu\text{m}$) as the triboelectric layer to increase the output signals as shown in Fig. 18(A) (i). A Kapton film

(150 μm) was fixed on the n-PTFE layer to increase the flexibility of the device and an ultra-thin Al foil (100 μm) was employed as both triboelectric layer and electrode. They have developed a resilient titanium strip as the keel structure (Fig. 18(A) (ii)), which significantly enhanced the mechanical behavior of the total structure and guaranteed solid contact and separation of the iTENG. To further augment the reliability of the iTENG and to avoid adhesion in the physiological environment, parylene C was deployed on the surface as a shell structure to form a hole-free coating layer. This “layer by layer” encapsulation strategy ensured the structural stability of the iTENG and its resistance to a complex internal environment. Basically, the PDMS layer was used to ensure the flexibility of the overall device to bend conveniently in response to the tiny movements. They have tested in-vitro electrical output of the iTENG before and after encapsulation by applying a periodic external mechanical force. Ten iTENGs with a unified specification were utilized in this experiment. Before encapsulation, the voltage and current reach $\sim 90\text{ V}$ and $\sim 12\text{ }\mu\text{A}$ respectively (Fig. 18(A) (vi)). After encapsulation the iTENG has been placed in phosphate-buffered saline (PBS) to test both the output signals and the stability in a physiological solution environment. The instantaneous current drops with increasing load resistance due to ohmic loss, while the voltage builds up (Fig. 18(A) (viii)). Consequently, at a load resistance of 10 M Ω , a power density of 107 mW/m² for the iTENG was achieved. The device can charge the capacitor up to 5.2 V within 150 s. They have also tested in-vivo experiment on animal model (male adult Yorkshire porcine, 30 kg) and an electrical output voltage of up to $\sim 14\text{ V}$, and the corresponding current up to $\sim 5\text{ }\mu\text{A}$ was achieved. With a heart rate of 80 bpm, a 1 μF capacitor can charge up to 2.8 V within 200 s using iTENG.

Liu *et al.* (2019a) explored a flexible self-powered endocardial pressure sensor (SEPS) made by TENG, as shown in Fig. 18(B). The TENG has been integrated with a surgical catheter for minimally invasive implantation. To imitatively evaluate the function of the SEPS for real-time biomedical monitoring in human bodies, they have selected male adult Yorkshire pigs (40 kg) as the animal model. To achieve minimally invasive implantation, they have fabricated a delivery system by integrating the miniature SEPS with a heparin-coated polyvinyl chloride (PVC) stretchable catheter, which is widely used in cardiopulmonary bypass surgery (Fig. 18(B) (iv)). The output signals of ECG, FAP, and SEPS were documented and compared under resting, arousing and active conditions, as exhibited in Fig. 18(B) (v). At the resting status (systolic FAP < 100 mmHg), a positive voltage of $\approx 80\text{ mV}$ was obtained, with both FAP and voltage remaining constant, indicating that the miniature and flexible device exerted little interruption on the stableness of cardiac functionality. The enlarged drawing of signals at the resting status is displayed in Fig. 18(B) (vi).

Hinchet *et al.* (2019) demonstrated a transcutaneous ultrasound energy harvesting system using capacitive triboelectric technology that charges a battery from an ex-vivo condition using ultrasound (US). They explored the use of a high-frequency vibrating and implantable triboelectric generator (VI-TEG) in vivo state for harvesting US. The VI-TEG with less than 1-mm-thick (Fig. 19(A) (iii)) was developed to be implanted underneath the skin ($\approx 10\text{ mm}$) (Fig. 19(A) (i)). They prepared a thin ($\approx 50\text{ }\mu\text{m}$ thick) and large membrane of perfluoroalkoxy (PFA), which is a copolymer of tetrafluoroethylene and perfluoroethers that vibrate under the pressure of US. Such a generator confirms easy and constant operation despite the variations in environment and usage conditions. The membrane was suspended on a thin Cu electrode (3.6 cm $\times$ 3.6 cm) on a flexible printed circuit board (PCB) and coated with Au (Fig. 19(A) (ii)); the air gap was 80 mm. The preliminary mechanical and acoustic simulations showed that the US vibration cannot pass via VI-TEG because of its reflection (Fig. 19(A) (iv)). The membrane vibrated in a multimode under a US excitation of 20 kHz (Fig. 19(A) (v)), developing multiple nodes and antinodes that moved up and down. The VI-TEG works in the single-electrode mode using the primary Cu/Au electrode, a small backside reference Cu electrode, and a triboelectric PFA membrane layer.

The VI-TEG can generate voltage peaks of $\approx 25\text{ V}$ at 40 M Ω impedance and current peaks of $\approx 1.3\text{ mA}$ at 1 Ω impedance. These outcomes correspond to a root mean square (RMS) voltage of $\approx 9.71\text{ V}$ and an RMS current of $\approx 427\text{ mA}$. The VI-TEG developed 450 mA at 33 k Ω , providing a maximum power of $\approx 6.74\text{ mW}$, which is equal to $\approx 0.872\text{ mW}$ of average constant power and a power density of $\approx 5.2\text{ W m}^{-2}$.

The VI-TEG was also kept under porcine tissue which is comparable to human skin in terms of composition and anatomy to realize the in-vivo capability (Fig. 19(B) (i–iii)). Transcutaneous electronic implants are usually located at a depth of $\approx 5\text{--}10\text{ mm}$. At 0.5 cm, the VI-TEG provides output signals of more than $\approx 2.4\text{ V}$ and $\approx 156\text{ mA}$ (Fig. 19(B), iv). The lowering in the voltage and current was caused by US attenuation. At 1.0 cm under layered tissues including the skin and the fat, the VI-TEG provides output signals of more than $\approx 1.93\text{ V}$ and $\approx 98.6\text{ mA}$ (Fig. 19(B), v). The power generating performance for VI-TEG was ≈ 4.78 and ≈ 2.81 times less than that in water and the BS, respectively, under porcine tissue, because of the improved acoustic impedance and attenuation in the different layers and media structure.

Solid-liquid contact based TENGs

Solid-liquid based TENGs have several promising applications owing to their portability compared to solid-solid based TENGs. Lin *et al.* (2013) have observed a solid-liquid TENG between a patterned polydimethylsiloxane pyramid array and water. After that various systems have been demonstrated to improve the performance of the TENGs with a fast headway in nanoscale materials and micro/nano fabrication strategies. Zhang *et al.* (2021) explored a solid-liquid based TENG where triboelectric effect is produced when the fluid stream moves through a cylinder at a specific point and interacts with the internal electrode. In this concept the triboelectric charges are generated without going through the electrostatic induction process between bottom electrode and the surface in the case of TENG. Such design successfully avoids the interfacial screening effect and effectively transfers triboelectric charges based on bulk effect. The nanogenerator consists of a dielectric layer tube (Polytetrafluoroethylene (PTFE) or ethylene propylene (FEP)), an outer terminal (Cu) and an inner cathode (Al). They suggested that due to the contact of the internal electrode with the liquid, the rate of charge flow inside the tube is dominated by the volume effect instead of the interfacial effect, resulting in a higher voltage (17 times higher than the interfacial effect) and therefore boosting the power output of the device

Fig. 19 Concept and design of the VI-TEG. A, (i) Illustration of US energy harvesting under skin using the VI-TEG. (ii) Exploded view of the VI-TEG structure. (iii) Front and back photo of the VI-TEG. (iv) Finite element method (FEM) simulation of US acoustic pressure propagation through water and the VI-TEG. (Fig. 20(A)). The fabricated device can generate an open-circuit voltage of ~904 V, which is ~17 times of its counterpart, ~52.8 V, and similar results are obtained from fluorinated (FEP) tubes. Moreover, the triboelectric output generation is also impacted by the type of flow dynamics – steady or unsteady flow. Ahn et al. (2020) studied the hydrodynamics of unsteady pipe flow and found that the output current from unsteady flow is 70 times higher than that of steady flow at a similar operating pressure (Fig. 20(B)). To increase the application scope, an unsteady type of peristaltic flow is also being used as the source of energy harvesting using the solid-liquid TENGs (Cheedarala et al., 2019). Using a peristaltic pump, liquid stream is driven through an elastomeric tubing, causing squeezing and restitution of the tubing and generating peristaltic flow, which leads to the movement of the liquid. Based

Table 4 The output performances of the various small scale TENGs reported in literature

Triboelectric materials	Area of TENG	Output performance			References
		Voltage (V)	Current (μ A)	Power density (mW m^{-2})	
PDMS and Al	12 mm $\times$ 12 mm	3.73	0.14	8.44	(Zheng <i>et al.</i> , 2014)
PLGA and PCL	20 mm $\times$ 30 mm	4	1	32.6	(Zheng <i>et al.</i> , 2016b)
PTFE and Al	38 mm $\times$ 38 mm $\times$ 9.5 mm	215	660	9800	(Bai <i>et al.</i> , 2013)
PTFE and Al	25 mm $\times$ 10 mm $\times$ 1.5 mm	14	5	107	(Zheng <i>et al.</i> , 2016a)
PTFE and Kapton	30 mm $\times$ 20 mm $\times$ 1 mm	10	4	—	(Zheng <i>et al.</i> , 2016a)
PDMS and Al	30 mm $\times$ 28 mm	230	94	128 mW/cm^3	(Wang <i>et al.</i> , 2012)
PTFE and Water	100 mm $\times$ 70 mm	300	13.5	140	(Zhao <i>et al.</i> , 2018)
PMMA and Water	1000 mm^2	22	4	2.83	(Wang <i>et al.</i> , 2020)

on the change in the flow rate, the elastomeric tubing will result in three different states squeezed, fully squeezed, or fully resituated and result in different rates of charge generation and, finally, different current peaks (Fig. 20(C)).

The output performance of some small scale based TENG devices is summarized in Table 4.

Magneto-Mechano-Electric Generator

MME energy conversion has been demonstrated using a ME composite in the form of a cantilever operating at its structural resonance and converting low-frequency magnetic noise into electricity (Annapureddy *et al.*, 2016; Priya *et al.*, 2007). An ME composite with piezoelectric PMN-PZT single crystal macro-fibers and Ni magnetostrictive plate was demonstrated to generate 0.73 mW power from 0.7 mT magnetic flux density by Annapureddy *et al.* (2016). The same group explored an MME generator ($45 \times 21 \text{ mm}^2$) made by PMN-PZT single crystal fiber and Ni-based magnetostrictive materials for low power devices, wireless sensor networks, and re-charging applications (Damjanovic, 1998). The MME generator has been shown to achieve power density of $0.46 \text{ mW cm}^{-3} \text{ Oe}^{-2}$ under a weak magnetic flux density of 160 μT at 60 Hz, without an external DC magnetic field.

Fig. 21 (A) Schematic of end forcing and distributed forcing MME generator and the harvesting performance under magnetic field around the wire carrying current. (B) The working mechanism of the ME coupled multilayered MME generator and output performance and application demonstration. Reproduced with permission from Sriramdas, R., Kang, M.G., Meng, M., *et al.*, 2020. *Advanced Energy Materials* 10, 1903689. Copyright 2020, WILEY-VCH Verlag GmbH & Co. KGaA, Weinheim. Lee, H., Sriramdas, R., Kumar, P., *et al.*, 2020. *Energy & Environmental Science* 13, 1462–1472. Copyright 2020. Royal Society of Chemistry.

Kambale *et al.* explored an MME generator with an ME structure (Kambale *et al.*, 2014), consisting of asymmetric (PZT ceramic fibers/Ni) and symmetric (Ni/PZT ceramic fibers/Ni) laminate structures. The symmetric structure developed a peak voltage of 0.3 V and an asymmetric structure developed an output of 2.5 V. The asymmetric structure developed maximum power of 6 μW at 1 Hz. Sriramdas *et al.* (2020) have demonstrated an MME harvester with large power amplification through distributed forcing (Fig. 21(A)) at a constant 60 Hz frequency. They fabricated an MME generator by adding 18 Metglas layers as magnetostrictive laminate and one layer of single-crystal fiber PMN-PZT composite. The thickness of crystal fiber was 200 μm , each Metglas layer thickness was 23 μm and the total thickness of the composite beam was 850 μm . They selected 3.96 g end mass to realize the first configuration. To obtain the fundamental frequency, 60 Hz, a mass of 7.6 g was attached at 33 mm from the clamped end which resulted in mass and length ratios of $m_r = 3.84$ and $l_r = 0.73$. In case of dual mass harvester the generated output voltage was 36.5 V, while the generated voltage was 24.7 V with just the end mass, at 1 mT flux density. Recently, Lee *et al.* (2020) have introduced a novel ME coupled MME generator (Fig. 21(B)) that provides 400% higher output power compared to the state-of-the-art, when operating at a magnetic flux density as low as 100 μT . The ME coupled MME generator develops a milliwatt power below 300 μT stray magnetic flux density. The device can also produce power under moderate to extremely low magnetic fields ($\leq 50 \mu\text{T}$), indicating its feasibility for harvesting energy for low power applications.

Kang *et al.* (2018) have explored a high-power MME harvester through amplified magneto-mechanical vibration for IoT applications (Fig. 22(A)). They fabricated MME generator using PZT as a piezoelectric layer and FBS as a magnetostrictive layer. To achieve high ME coupling, in addition to the piezomagnetic coefficient of the FBS, the overall structural design was optimized for enhancing strain amplitude in the piezoelectric macrofiber composite. To quantify the influence of strain amplitude, multilayer FBS laminates were utilized with different number of layers (5, 10, 15, and 20 layers), which resulted in different elastic stiffnesses in the overall structure. The fabricated ME coupled MME harvester with 20 layers was found to generate high electrical power of $\approx 180 \mu\text{W}_{\text{peak}}$ and $\approx 9.8 \text{ mW}_{\text{peak}}$ under an AC magnetic field of 0.1 and 1 mT, respectively. The power at 1 mT is enough to turn on 80 LED arrays and charge 10 mF capacitor. The textured Fe-Ga alloy sheet containing magnetostrictive and anisotropic PMN-PZ-PT piezoelectric single-crystal fibers based low-cost and scalable high-performance MME generator has been explored by Annpureddy *et al.* (2018) They fabricated an MME generator by covering the top and bottom of the PMN-PZT single crystal fiber composite using Cu electrodes. It is noteworthy that the Fe-Ga based MME generator demonstrated a strong ME coupling of $\alpha_{\text{ME}} = 1330 \text{ V cm}^{-1} \text{ Oe}^{-1}$, without any magnetic bias field, which is 170% larger than that of a Ni-based MME generator explored in the community. The MME generator was found to generate large DC power density of 3.22 mW/cm^3 , with high voltage of

Fig. 22 (A) ME composite and energy harvesting scheme using MME harvester is shown schematically. (B) Schematic of optimized MFC concentrating the magnetic field in an MME generator, theoretical simulation model of the MFC, density distribution in the magnetostrictive layer under a magnetic field of 8 Oe, magneto-electric voltage coefficient, and measurement setup. (C) The output performance of MFC integrated MME generator. Reproduced with permission from Kang, M.G., Sriramdas, R., Lee, H., *et al.*, 2018. *Advanced Energy Materials* 8, 1703313. Copyright 2019, WILEY-VCH Verlag GmbH & Co. KGaA. Weinheim. Song, H., Patil, D.R., Yoon, W.-H., *et al.*, 2020. *Energy & Environmental Science* 13, 4238–4248. Copyright 2019, Royal Society of Chemistry.

212 $V_{\text{peak-peak}}$ (>330% improvement, as compared with the Ni-based MME generator), and current of $52 \mu\text{A cm}^{-2}$ (>250% improvement) under a 60 Hz AC magnetic flux density of $700 \mu\text{T}$.

In a recent study [Song *et al.* \(2020\)](#) have introduced an MME generator made by an anisotropic 32 mode Mn-doped $\text{Pb}(\text{Mg}_{1/3}\text{Nb}_{2/3})\text{O}_3\text{-PbZrO}_3\text{-PbTiO}_3$ (PMN-PZ-PT) SCF, directly integrated with a Ni cantilever structure and a NdFeB permanent magnet proof mass. They have utilized a magnetic flux concentrator (MFC) in the MME generator to increase the power density and measure output performance with and without MFC (**Fig. 22(B, C)**). The MFC can enhance the power of the MME generator by enhancing the ME coupling and magnetic forcing simultaneously, thereby influencing the intrinsic mechanism responsible for the output performance. The MME generator with the MFC was observed to generate a maximum power of 3.33 mW, which was 285% of that of the condition without the MFC (1.17 mW) under a weak magnetic field of 8 Oe ($= 8 \text{ G} = 800 \mu\text{T}$ in the air), which was sufficient to charge the 2.2 mF storage capacitor within 13 s and continuously operate an IoT sensor for a long period. They have achieved an optimum α_{ME} value of $0.84 \text{ V cm}^{-1} \text{ Oe}^{-1}$ which was obtained at $H_{\text{dc}} = 0 \text{ Oe}$, validating the intrinsic self-biasing nature of the MME generator, that eliminated the use of a DC electromagnet for additional study. The nature of self-bias of the MME generator can be assigned to the hysteretic magnetic behavior of the Ni foil, which comes from the size-dependent demagnetization effect associated with Ni foil and coercive field of the Ni foil owing to macro-sized domains with long-range ordering. The output performance of different MME generators are compared in **Table 5**.

Applications

Piezo/Triboelectric nanogenerators

Mechanical energy harvesting through PENGs and TENGs has gained attention due to the diversity of designs to directly convert mechanical energy into electricity for various wearable and portable integrated applications. This energy harvesting technology can be applied in applications such as tactile sensors, resonators, medical sensors, actuators, and various portable/smart electronics. The PENGs/TENGs are relevant for future biomedical applications to detect various kinetic energies, generated from respiration or

heartbeat or arterial pulse movements, or even blood flow (Fig. 23). Presently, there is interest in developing in-vivo biomedical applications through biomechanical energy harvesting for the operation of implanted-medical-devices (IMDs). The harvesters enabled using a single crystalline piezoelectric PMN-PT thin film can be used as a self-powered artificial pacemaker. This material has been demonstrated in providing real-time functional electrical stimulation for stimulating the artificial heart beating in a live rat. The muscle-driven PENG can generate biomechanical energy from the heartbeat and breath of a live rat so it may be applicable for biomedical applications. The TENG can also charge the battery of a pacemaker, which is crucial for the implementation of implantable devices. Some important biomedical applications of TENGs include IMDs, cardiac monitoring sensors, laser curing systems for osteogenesis, nerve cell stimulation devices, and real-time monitoring sensors of respiratory rate, heart rate, and blood pressure.

Magneto-mechano-electric generators

MME generator can be used as a sustainable power source for IoT sensors and wireless communication systems installed in smart homes, factories, and have potential biomedical applications. ME coupled MME generator has been demonstrated to power

several LEDs without a capacitor, and operate multiple sensors and Bluetooth data communication systems simultaneously. The MME generator can be used for structural health monitoring (SHM) of outdoor power cables, as continuous magnetic field is present for the MME generator. MME generator has been demonstrated to power standalone IoT temperature and humidity sensors and peripheral components. The demonstration of powering smart electronics using MME generators is shown in Fig. 24. Apart from energy harvesting, the ME coupled composites find several applications in magnetic sensors, current sensors, tunable filters and resonators. On demand drug release, gastrointestinal tract examination and neural activity stimulation using ME nanoparticles are some of the potential biomedical applications. Furthermore, ME materials have potential applications in non-volatile random access memory with multiple memory states offering high memory density (Vopson, 2015). ME antenna is another possible application for transmitting data with less ohmic losses and without capacitive or inductive loadings (Petrov *et al.*, 2008). Nevertheless, ME transducers in the form of energy harvesters have been demonstrating considerable power densities even from weak and low-frequency magnetic fields. A comparative analysis of the three types of generators according to their output performance is presented in Table 6.

Remarks and Future Challenges

This chapter discussed the development of small-scale piezo/tribo/magneto-mechano-electric devices in energy harvesting and various IoT applications. The fabrication process of TENG devices is relatively simple and convenient, with low cost. The piezoelectric and MME generators can be realized with relatively easier and simpler architecture. All three techniques are of great

Table 6 Comparison of the output performance of MME generator with that of previously reported piezo/triboelectric energy harvesters

Harvesting Technique	Materials	Output Performance			Frequency (Hz)
		Voltage (V)	Current (μ A)	Power/power density	
MME Generator	Ni/PMN-PZ-PT	2.5	–	0.046 mW/cm ³	60
	Textured Fe-Ga/SCMF PMN-PZ-PT	76.5	178	3.22 mW/cm ³	60
	Ni/low-loss PMN-PZ-PT	24	120	2.1 mW/cm ³	60
Triboelectric Nanogenerator	PZT/polyethylene terephthalate	6	0.045	0.2 mW/cm ³ (peak power)	1
	PDMS/Al	230	94	128 mW/cm ³	6
	PTFE/Al	215	660	9.8 mW/cm ²	10
	Kapton/polyester	3.3	0.6	10.4 mW/cm ³ (peak power)	5
Piezoelectric Nanogenerator	PMN-PT nanobelts	6	102	0.3 mW (peak power)	–
	PZT thick film	70	12	0.2 mW	0.4
	PMN-PZT single crystals	80	17	0.26 mW	2

interest in the energy harvesting community as the devices achieve excellent power densities. The studies show that the power density of small area generators depends on several parameters such as material structures, device fabrication, and impedance matching circuitry, which are essential for practical applications. Impedance matching in triboelectric harvesting technique is different from piezoelectric and MME generators, and hence, appropriate circuit development is vital to achieve higher power densities. Several demonstrations of energy harvesting and its applications towards IoT have been reported in the research community. Further developments in miniaturization to maintain higher power output, and integrated power management circuitry for charging batteries is required.

In order to develop high power density and powering electronics using the MME generator from a commercial viewpoint, some additional efforts are required such as (1) materials combination and selection criteria specific to small area harvesting, have to be established to achieve the optimum performance, (2) fundamental studies on magnetostriction based power conversion efficiency have to be examined, (3) the feasibility and biocompatibility of the integrated implantable devices is important for in-vivo studies, and (4) the novel material development using nanotechnology to achieve ultra-high sensitivity at small (micro- or nano size) scales. The small-scale energy harvesting solutions will have a tremendous impact on the application of piezoelectric, triboelectric, and magneto-mechano-electric energy harvesting for the WSNs and IoT technologies. We believe that this chapter will provide guidance not only to the beginners by introducing the essential fundamental concepts but also to the research scientific community through the state-of-the-art demonstrations and the future directions in advancing the small-scale harvesting technologies.

Multilayer Ceramic Actuators

K Uchino, The Penn State University, University Park, PA, USA

© 2016 Elsevier Inc. All rights reserved.

Piezoelectric and electrostrictive ceramic materials have become key components in smart actuator/sensor systems for use as precision positioners, miniature ultrasonic motors, and adaptive mechanical dampers. In particular, multilayer (ML) structures have been widely investigated in order to improve their reliability and to expand their applications. Developments in the USA, Japan, and Europe are compared.

Trends in Ceramic Actuators

Piezoelectric actuators are forming a new field midway between electronic and structural ceramics (Uchino, 1993, 1994, 1995b, 1996). Application fields are classified into three categories: positioners, motors, and vibration suppressors. The manufacturing precision of optical instruments such as lasers and cameras, and the positioning accuracy for fabricating semiconductor chips, which are adjusted using solid-state actuators, is of the order of 0.1 μm . Regarding conventional electromagnetic motors, tiny motors smaller than 1 cm are often required in office or factory automation equipment, and are rather difficult to produce with sufficient energy efficiency. Ultrasonic motors whose efficiency is insensitive to size are superior in the minimotor area. Vibration suppression in space structures and military vehicles using piezoelectric actuators is also a promising technology.

ML structures are mainly used for practical applications because of their low drive voltage, high energy density, quick response, and long lifetime (Yoshikawa and Shrout, 1993; Uchino, 1995a). Fig. 1 illustrates ML, multimorph, and ML-moonie structures, which will be covered in this chapter. Investigations have focused on the improvement of reliability and durability in ML actuators (MLAs).

This chapter reviews the investigations of device structures, reliability issues, and applications of MLAs, comparing the developments in the USA, Japan, and Europe.

ML Structures

Two preparation processes are possible for ML ceramic devices: one is a cut-and-bond method and the other is a tape-casting method. The tape-casting method requires expensive fabrication facilities and sophisticated techniques, but is suitable for the mass-production of thousands of pieces per month. Tape casting also provides thin dielectric layers, leading to low drive voltages of 40–100 V (Dibbern, 1995; Takada *et al.*, 1994).

An MLA with interdigital internal electrodes has been developed by Tokin (Ohashi *et al.*, 1993a,b). In contrast to the conventional electrode configuration in Fig. 1, line electrodes are printed on piezoelectric ceramic green sheets, and are stacked in such a way that alternating electrode lines are displaced by one-half pitch (see Fig. 2). This actuator generates motions at right angles to the stacking direction using the longitudinal piezoelectric effect. Long ceramic actuators up to 74 mm in length are manufactured.

A three-dimensional positioning actuator with a stacked structure has been proposed by PI Ceramic (Fig. 3), in which shear strain is used to generate x and y displacements (Bauer and Moller, 1995).

Composite actuator structures called ‘moonies’ and ‘cymbals’ have been developed at Penn State University to provide characteristics intermediate between the ML and bimorph actuators. These transducers exhibit an order of magnitude larger displacement than the ML, and much larger generative force with quicker response than the bimorph (Sugawara *et al.*, 1992; Onitsuka *et al.*, 1995). The device consists of a thin ML piezoelectric element and two metal plates with narrow moon-shaped cavities bonded together as shown in Fig. 1. A moonie $5 \times 5 \times 2.5$ mm in size can generate a 20 μm displacement under 60 V, eight times as large as the displacement of a ML of the same size (Goto *et al.*, 1992). This new compact actuator has been used to make a miniaturized laser beam scanner (Goto *et al.*, 1992). Moonie/cymbal characteristics have been investigated for various constituent materials and sizes (Tressler *et al.*, 1994; Dogan *et al.*, 1994).

Actuator Materials

Actuator materials are classified into three categories: piezoelectric, electrostrictive, and phase-change materials. Modified lead zirconate titanate (PZT, $\text{Pb}(\text{Zr,Ti})\text{O}_3$) ceramics are the leading materials for piezoelectric applications. The PLZT ($(\text{Pb,L a})(\text{Zr,Ti})\text{O}_3$) 7/62/38 compound is one such composition (Furuta and Uchino, 1986). The strain curve is shown in Fig. 4(a) (left). When the applied field is small, the induced strain, x , is nearly proportional to the field, $E(x=dE$, where d is called the piezoelectric constant). As the field becomes larger (i.e., greater than about 1 kV cm^{-1}), however, the strain curve deviates from this linear trend and

Fig. 1 Examples of multilayer, multimorph, and multilayer-moonie structures.

Fig. 2 Structure of an internal interdigital electrode actuator.

significant hysteresis is exhibited owing to polarization reorientation. This sometimes limits the usage of such materials in actuator applications that require nonhysteretic response.

An interesting new family of actuators has been fabricated in Germany from a barium stannate titanate system ($\text{Ba}(\text{Sn,Ti})\text{O}_3$) (von Cieminski and Beige, 1991). The useful property of $\text{Ba}(\text{Sn}_{0.15}\text{Ti}_{0.85})\text{O}_3$ is its unusual strain curve, in which the domain reorientation occurs only at low fields, and there is then a long linear range at higher fields (Fig. 4(a) (right)); i.e., the coercive field is unusually small. Moreover, this system is particularly intriguing since it contains no lead ions, an essential feature as ecological concerns grow in the future.

The second category of actuators is based on electrostriction as in PMN ($\text{Pb}(\text{Mg}_{1/3}\text{Nb}_{2/3})\text{O}_3$)-based ceramics, developed in the USA. Although a second-order phenomenon of electromechanical coupling ($x = ME^2$, where M is the electrostrictive constant), it can be extraordinarily large (more than 0.1%) (Cross et al., 1980). An attractive feature of these materials is the near absence of

Fig. 3 Three-dimensional controllable multilayer piezoelectric actuator.

Fig. 4 Electric field-induced strains in ceramics: (a) piezoelectric $(\text{Pb},\text{La})(\text{Zr},\text{Ti})\text{O}_3$ and $\text{Ba}(\text{Sn},\text{Ti})\text{O}_3$; (b) electrostrictive $\text{Pb}(\text{Mg}_{1/3}\text{Nb}_{2/3},\text{Ti})\text{O}_3$; (c) phase-change material $\text{Pb}(\text{Zr},\text{Sn},\text{Ti})\text{O}_3$.

hysteresis (**Fig. 4(b)**). The superiority of PMN over PZT has been demonstrated in a scanning tunneling microscope (STM) (Uchino, 1988). The PMN actuator can provide extremely small distortion of the image even when the probe is scanned in the opposite direction.

The third category is based on phase-change-related strains, i.e., polarization induced by switching from an antiferroelectric to a ferroelectric state (Uchino and Nomura, 1983). **Fig. 4(c)** shows the field-induced strain curves taken for the lead zirconate stannate $(\text{Pb}_{0.99}\text{Nb}_{0.02}((\text{Zr}_x\text{Sn}_{1-x})_{1-y}\text{Ti}_y)_{0.98}\text{O}_3)$ -based system. The longitudinally induced strain reaches more than 0.3%, which is much larger than that expected in normal piezoelectrics or electrostrictors. A rectangular hysteresis in **Fig. 4(c)** (left), referred to as a 'digital displacement transducer' because of the two on/off strain states, is interesting. Moreover, this field-induced transition

Fig. 5 Various internal electrode configurations in multilayer actuators: (a) interdigital, (b) plate-through, (c) slit-insert, and (d) float electrode.

exhibits a shape memory effect in appropriate compositions (Fig. 4(c) (right)). Once the ferroelectric phase has been induced, the material ‘memorizes’ its ferroelectric state even under zero-field conditions, although it can be erased with the application of a small reverse bias field (Furuta *et al.*, 1992). This shape memory ceramic is used in energy-saving actuators.

Reliability of MLAs

As application fields expand, the reliability and durability issues of MLAs become increasingly important. The reliability of ceramic actuators depends on a number of complex factors, which can be divided into three major categories: reliability of the ceramic itself, reliability of the device design, and the drive technique.

Compositional changes of actuator ceramics and the effect of doping are primary issues used in stabilizing the temperature and stress dependence of the induced strains. A ML piezoactuator for use at high temperatures (150 °C) has been developed by Hitachi Metal, using Sb_2O_3 -doped $(\text{Pb},\text{Sr})(\text{Zr},\text{Ti})\text{O}_3$ ceramics (Watanabe *et al.*, 1993). Systematic data on uniaxial stress dependence of piezoelectric characteristics have been collected on various navy PZT materials (Zhang *et al.*, 1996). Grain size and porosity control of the ceramics are also important in controlling the reproducibility of actuators (Okada *et al.*, 1993). Aging phenomena, especially the degradation of strain response, are, in general, strongly dependent on the applied electric field as well as on temperature, humidity, and mechanical bias stress (Sakai *et al.*, 1992).

The device design strongly affects its durability and lifetime. Silver electrode metal tends to migrate into the piezoceramic under a high electric field in high humidity. Silver–palladium alloys suppress this behavior effectively. Resistive coatings of the device should also be taken into account (Takada, 1992). To overcome electrode delamination, improved adhesion can be realized by using a mesh-type electrode or an electrode material with mixed metal and ceramic (the matrix composition) powders. Pure ceramic electrode materials have also been developed using semiconductive perovskite oxides (barium titanate-based PTCR ceramics) (Abe *et al.*, 1986). The lifetime characteristics of a MLA with applied d.c. or unipolar a.c. voltage at various temperatures (Nagata and Kinoshita, 1994, 1995b) and at various humidity levels (Nagata and Kinoshita, 1995a) have been investigated. The relationship between the logarithm of the lifetime and the reciprocal of absolute temperature shows linear characteristics similar to Arrhenius-type ones. Nevertheless, the degradation mechanism remains a critical problem.

In MLAs, reduction of the tensile stress concentration around the internal electrode edge of the conventional interdigital configuration is the central problem. Regarding the destruction mechanism of ML ceramic actuators, systematic data collection and analysis have led to considerable progress (Furuta and Uchino, 1993, 1994; Aburatani *et al.*, 1994; Wang and Singh, 1995; Cao and Evans, 1994; Schneider *et al.*, 1994; Suo, 1993; Hao *et al.*, 1996). Two typical crack patterns are generated in a conventional interdigital ML device: one is a Y-shaped crack located on the edge of an internal electrode, and the other is a vertical crack located in a layer adjacent to the top or bottom inactive layer, connecting a pair of internal electrodes.

To overcome this crack problem, three electrode configurations have been proposed, as illustrated in Fig. 5: plate-through, interdigital and slit, and interdigital and float electrode types. The ‘float electrode’ type is an especially promising design, which can be fabricated using almost the same process as the conventional MLA, and leads to much longer lifetimes (Aburatani *et al.*, 1995). An empirical rule, ‘the thinner the layer, the tougher the device’ (Aburatani *et al.*, 1994; Furuta and Uchino, 1994), is also very intriguing, and will be more theoretically investigated in the near future.

Failure detection or lifetime prediction methods are expected to increase remarkably the reliability of MLAs. Acoustic emission and surface potential monitoring are promising methods (Uchino and Aburatani, 1994). A modified MLA has been developed at Pennsylvania State University containing a strain gage as an internal electrode (Sano *et al.*, 1993). This internal strain gage electrode can detect the crack initiation sensitively and monitor the field-induced strain (Aburatani and Uchino, 1996).

Regarding drive techniques for ceramic actuators, pulse drive and a.c. drive require special attention; the vibration overshoot associated with a sharp-rise step/pulse voltage causes a large tensile force, leading to delamination of the multistacked structure, while long-term application of a.c. voltage generates considerable heat. A special pulse drive technique using a mechanical bias stress is required in the first case, and heat generation can be suppressed by changing the device design. An analytical approach to the heat generation mechanism in MLAs has been reported, indicating the importance of larger surface area (Zheng *et al.*, 1996). Heat generation in piezoelectric ceramics is mainly attributed to the P–E hysteresis loss under large electric field drive (Hirose *et al.*,

Table 1 Ceramic actuator developments in the USA, Japan, and Europe (as of 2000)

	USA	Japan	Europe
Target	Military-oriented product	Mass consumer product	Laboratory equipment
Category	Vibration suppressor	Minimotor, positioner	Minimotor, positioner, vibration suppressor
Application field	Space structure military vehicles	Office equipment, cameras, precision machines, automobiles	Laboratory stage-stepper, aircraft, automobiles, hydraulic systems
Actuator size	Up-sizing (30 cm)	Down-sizing (1 cm)	Intermediate size (10 cm)
Major manufacturer	AVX/Kyocera, Morgan Matroc, Itek, Opt. Systems, Burleigh, AlliedSignal	Tokin Corp., NEC, Hitachi Metal, Mitsui-Sekka, Canon, Seiko Instruments	Philips, Siemens, Hoechst Ceram Tec., Ferroperm, Physik Instrument, Noliac

1995b; Takahashi *et al.*, 1995). For ultrasonic motors, antiresonance drive is preferable to resonance drive because of higher efficiency and lower heat generation for the same vibration level (Hirose *et al.*, 1995a).

Applications of MLAs

Table 1 compares a variety of ceramic actuator developments in the USA, Japan, and Europe (as of 2000). Additional details are described below.

USA

The principal target is military-oriented applications such as vibration suppression in space structures and military vehicles. Substantial increase in the size of the actuators is required for these purposes.

A typical example is found in the aircraft wing proposed by NASA (Heeg, 1993). A piezoelectric actuator is installed near the support of the wing, allowing immediate suppression of unwanted mechanical vibrations. Several publications have reported on damper and noise cancellation applications (Mather and Tran, 1993; Agrawal and Bang, 1993).

Passive dampers constitute another important application of piezoelectrics, where mechanical noise vibration is radically suppressed by the converted electric energy dissipation through Joule heat when a suitable resistance, equal to an impedance of the piezoelectric element of $1/\omega C$, is connected to the piezoelement (Uchino and Ishii, 1988).

A widely publicized application took place with the repair of the Hubble telescope launched by the Space Shuttle. ML PMN electrostrictive actuators corrected the image by adjusting the phase of the incident light wave (Fig. 6; Wada, 1993). PMN electrostrictors provided superior adjustment of the telescope image because of negligible strain hysteresis.

Fig. 7 Inchworm using multilayer piezoelectric actuators.

Fig. 8 Monolithic multilayer piezoelectric linear motor.

Japan

Japanese industries seek to develop mass-produced consumer products, especially minimotors and micro-positioners, aiming at applications such as office equipment and cameras/video cameras. Tiny actuators smaller than 1 cm^3 are the main focus in these products.

A dot matrix printer was the first widely commercialized product using ML ceramic actuators (Yano *et al.*, 1984). Each character formed by such a printer is composed of a 24×24 dot matrix in which a printing ribbon is impacted by a multiwire array. The printing element is composed of a ML piezoelectric device with a sophisticated hinge lever magnification mechanism. The magnification by a factor of 30 results in an amplified displacement of 0.5 mm and an energy transfer efficiency greater than 50%. A modified impact printer head has been developed by Tokin, using new interdigital internal electrode-type actuators, which has lowered production costs (Ono and Fuda, 1994). A color ink-jet printer has also been commercialized by Seiko Epson, using ML piezo-actuators (Yonekubo, 1995).

Automotive applications by Toyota Motor have been increasing. MLAs have been introduced to an electronically controlled suspension (Fukami *et al.*, 1994) and a pilot injection system for diesel engines has been developed (Abe *et al.*, 1994).

Efforts have been made to develop high-power ultrasonic vibrators as replacements for conventional electromagnetic motors. The ultrasonic motor is characterized by 'low speed and high torque,' which is contrasted with the 'high speed and low torque' of electromagnetic motors. After the invention of π -shaped linear motors (Tohda *et al.*, 1989), various modifications have been reported (Funakubo *et al.*, 1995; Saigoh *et al.*, 1995). The Mitsui Petrochemical model is of particular interest because the motor body is composed of only one component prepared by a co-firing method, as illustrated in Fig. 7 (Saigoh *et al.*, 1995). A maximum speed of 200 mm s^{-1} and a maximum thrust of 60 gf (0.6 N) has been reported for this motor.

Camera motors use a traveling elastic wave induced by a thin piezoelectric ring. A ring-type slider in contact with the 'rippled' surface of the elastic body bonded onto the piezoelectric can be driven in both directions by exchanging the sine and cosine voltage inputs. Another advantage is its thin design, making it suitable for installation in cameras as an automatic focusing device. Nearly 80% of the exchange lenses in Canon's EOS camera series have been replaced by ultrasonic motor mechanisms (Uchino, 1995c).

Intriguing research programs are underway in Japan on the vibration damping of earthquakes, using piezoelectric actuators (Shimoda *et al.*, 1992; Fujita, 1994). Active damping of a ML piezoactuator has been tested using an actual size H-type steel girder, and has been verified to be effective during earthquakes.

Europe

Ceramic actuator development has begun in Europe with a wide range of research topics. A focus of several major manufacturers is on laboratory equipment products such as laboratory stages and steppers with rather sophisticated structures.

Fig. 8 shows a walking piezomotor with four multilayer actuators by Philips (Koster, 1994). Two short actuators function as claspers while the longer two provide a proceeding distance in an inchworm mechanism. Physik Instrumente has developed more complicated two-leg type walkers (Gross, 1994).

Conclusions

The early 1980s saw the start of the intensive development of piezoelectric actuators in Japan, which then spread worldwide. The focus has been shifted to practical device applications. This chapter has reviewed several reliability issues of ML ceramic actuators as well as new actuator structures, and has compared the development of applications in the USA, Japan, and Europe.

The markets in the USA are chiefly limited to military and defense applications, and it is difficult to estimate the amount of sales. Navy needs include smart submarine skins, hydrophone actuators, and propeller noise cancellation. Smart aircraft skins are an air force objective, while the army requires helicopter rotor twisting, aeroservoelastic control, and cabin noise/seat vibration cancellation.

In Japan piezoelectric camera shutters (Minolta) and automatic focusing mechanisms in cameras (Canon), dot matrix printers (NEC), and part-feeders (Sanki) are now commercialized and mass-produced by tens of thousands of pieces per month. During commercialization, new designs and drive-control techniques of ceramic actuators have been developed. A number of patent disclosures have been generated by NEC, TOTO Corporation, Matsushita Electric, Brother Industry, Toyota Motors, Tokin, Hitachi Metal, and Toshiba.

Annual sales in 2005 (expecting the economic recovery in Japan) of ceramic actuator units, camera-related devices, and ultrasonic motors are estimated to reach \$500 million, \$300 million, and \$150 million, respectively. Regarding the final actuator-related products, \$10 billion is a realistic goal (Uchino, 1995c).

Future research trends can be divided in two ways: increasing the size of space structures and decreasing that of office equipment. Further decrease in size will also be required in medical diagnostic applications such as blood test kits and surgical catheters.

Key concerns for the future of ML ceramic actuators are 'miniaturization' and 'hybridization.' Layers thinner than 10 μm will be introduced in actuator devices replacing 100 μm sheets. Piezoelectric thin films compatible with silicon technology are a focus in microelectromechanical systems. Ultrasonic rotary motors as small as 2 mm in diameter (Flynn *et al.*, 1992) and a two-dimensional micro-optical scanner (Goto, 1994), both of which are fabricated on a silicon membrane, are good examples.

Nonuniform configurations or heterostructures of different materials, layer thickness, or electrode patterns will be adopted for practical devices. Functionally gradient piezoelectric actuators now being proto-typed indicate a new trend (Kim *et al.*, 1992).

Appendix

Fifteen years passed after authoring the above chapter. Though various researches have been explored during this period, the basic researches introduced in this chapter still remain important. Thus, in order to save the publication company's labor, the author decided to put only Appendix in this updated chapter for introducing the most essential three new researches: Pb-free piezoelectric materials, base metal (Cu) internal electrode, and diesel injection valve application.

A1 Pb-Free Piezoelectric Materials

Twenty-first century is called 'The Century of Environmental Management.' In 2006, European Community started RoHS (Restrictions on the use of certain Hazardous Substances), which explicitly limits the usage of lead (Pb) in electronic equipment. Basically, we may need to regulate the usage of PZT, most famous piezoelectric ceramics, in the future. The Japanese and European communities may experience governmental regulation on the PZT usage in these 10 years. Pb (lead)-free piezo-ceramics have started to be developed after 1999. The share of the patents for bismuth compounds (bismuth layered type and $(\text{Bi,Na})\text{TiO}_3$ (BNT) type) exceeds 61%. This is because bismuth compounds are easily fabricated in comparison with other compounds. Note that the toxicity of Bi^{3+} is not very low compared with Pb^{2+} , but that a regulation may not be proposed because this atomic element is not familiar to politicians fortunately. $(\text{Na,K})\text{NbO}_3$ (NKN) systems exhibit the highest performance because of the morphotropic phase boundary usage. Fig. A1 shows the current best data reported by Toyota Central Research Lab, where strain curves for oriented and unoriented $(\text{Na,K,Li})(\text{Nb,Ta,Sb})\text{O}_3$ ceramics are shown (Saito *et al.*, 2004). Note that the maximum strain reaches up to 1500×10^{-6} , which is equivalent to the PZT strain. Drawbacks include their sintering difficulty and the necessity of the

Fig. A1 Strain curves for oriented and unoriented (K,Na,Li)(Nb,Ta,Sb)O₃ ceramics.

sophisticated preparation technique (topochemical method for preparing flaky raw powder). Since the crystallographically-oriented films are obtained via the tape cast technology of flaky powders, this NKN preparation is very suitable to the ML devices. Tungsten-bronze (TB) types are another alternative choice for resonance applications, because of high Curie temperature and low loss. Refer to a review paper on Pb-free piezoelectrics by T. Takenaka (Takanaka, 2005).

Taiyo Yuden, Japan developed micro ultrasonic motors using non-Pb ML piezo-actuators (Doshida, 2009). Their composition is based on TB ((Sr,Ca)₂NaNb₅O₁₅) without heavy metal or even K (potassium seems to be a little toxic in comparison with Na). The basic piezoelectric parameters in TB ($d_{33}=55\sim80\text{ pC N}^{-1}$, $TC=300\text{ }^{\circ}\text{C}$) are not very attractive. However, once the c-axis oriented ceramics are prepared, the d_{33} is dramatically enhanced up to 240 pC N^{-1} . Further since the Young's modulus $Y_{33}^E=140\text{ GPa}$ is more than twice of that of PZT, the higher generative stress is expected, which is suitable to ultrasonic motor applications.

Taiyo Yuden developed a sophisticated preparation technology for fabricating oriented ceramics with a ML configuration: that is, preparation under strong magnetic field, much simpler than the Toyota's flaky powder preparation. Since most of piezo-ceramics are diamagnetic, the ceramic powder suspended in slurry will be aligned along its magnetically-stable axis under a strong magnetic field (such as 10 T). Because the polarization axis in their particular TB composition corresponds to the magnetically-unstable axis, they used the magnetic field parallel to the green sheet. A cut-green-sheet was rotated practically under steady magnetic field during drying period. These oriented green sheets were electroded, laminated, and sintered. They reported beautiful crystal orientation degree of the sintered product with Lotgering factor 0.9 (Doshida, 2009).

Fig. A2(a) shows their compact rotary ultrasonic motor with a piezoelectric MLA. A canti-lever rod is wobbled by a 2×2 arrayed MLA element, driven by a four-phase voltage (sine, cosine, -sine, and -cosine). They fabricated monolithic 2×2 arrayed elements with the size $2.6\times2.6\times1.1\text{ mm}^3$ including buffers with layer thickness as thin as $18\text{ }\mu\text{m}$ [Refer to Fig. A2(b) and (c)]. Because of this layer thinness and dramatic enhancement in the piezoelectric performance owing to the magnetic field alignment, the ultrasonic motor was successfully driven under only $3\text{ V}_{\text{p-p}}$ which is low enough to be adopted in mobile phones without coupling a step-up drive circuit.

A2 Cu Electrodes for ML Actuators

The internal electrode material of choice of the conventional ceramic ML devices were Ag/Pd, as it was in capacitors. However, owing to the Russian economy crisis in the late 1990s, palladium price increased dramatically with a peak in 2000, 10 times higher than 1990. Because of this raw material cost change, capacitor industries started to use Ni (Base metal) internal electrode. Though the price of Pd is stabilized now, the effort on the cheaper material usage is continuing. The piezo-actuator industry was a little behind to shift to use widely the Cu internal electrode. The piezo-industries are still using Ag/Pd or Pt for the internal electrodes. TDK-EPCOS started to commercialize the Cu embedded ML actuators for the diesel injection valve application, in which the

Fig. A2 (a) Compact rotary ultrasonic motor with a piezoelectric multilayer actuator, (b) 2×2 arrayed element, and (c) cross-section view of the $18 \mu\text{m}$ -layer ML element.

Fig. A3 Common rail type diesel injection valve with a piezoelectric multilayer actuator. [Courtesy by Denso Corporation.]

actuator cost is the major bottleneck at present (Boecking and Sugg, 2006). Another merit of the Cu electrode over Ag/Pd is the depression of the electrode metal diffusion into PZT ceramic layers.

A3 Diesel Injection Valve

Diesel engines are recommended rather than regular gasoline cars from the energy conservation and global warming viewpoint. Why? We need to consider the total energy of gasoline production; well-to-tank and tank-to-wheel. The energy efficiency, measured by the total energy required to realize unit drive distance for a vehicle (MJ km^{-1}), is of course better for high octane gasoline than diesel oil. However, since the electric energy required for purification is significant, the gasoline is inferior to diesel. As well known, the conventional diesel engine, however, generates toxic exhaust gases such as SO_x and NO_x . In order to solve this problem, new diesel injection valves were developed by Siemens, Bosch and Toyota with piezoelectric ML actuators. Fig. A3 shows a common rail type diesel injection valve (Fujii, 2005).

In order to eliminate toxic SO_x and NO_x and increase the diesel engine efficiency, high pressure fuel and quick injection control are required. In the engine one cycle (typically 60 Hz), the multiple injections should be realized in a very sharp shape (typically seven injections). For this purpose, piezoelectric actuators, specifically ML types, were adopted. The highest reliability of these devices at an elevated temperature (150°C) for a long period (10 years) has been achieved (Fujii, 2005). Note that the piezoelectric actuator is a key component to increase the burning efficiency and minimize the toxic exhaust gas elements.

Historical Development

In 1943–45, Fort Monmouth Signal Laboratory developed the very first tape-casting machine and tape casting compositions (Crowley *et al.*, 1945). Later, Massachusetts Institute of Technology utilized tape casting in 1947 and reported a thin sheet of a ceramic capacitor (Howatt *et al.*, 1947). After that, the Al_2O_3 substrate was reported by Howatt in 1952 (Howatt and Metuchen, 1948). The ultimate development of multilayer glass–ceramic substrates started in the early 1970s when IBM Corporation reported Al_2O_3 , ZnZrSiO_5 and CaSiO_3 with a low melting disilicate vitreous glass phase as the first example of LTCC (Charles and Fishkill, 1967). Thereafter, the substrate technology grew with the labels of high temperature co-fired ceramics (HTCC), low-temperature co-fired ceramics (LTCC), and recently ultra-low temperature co-fired ceramics (ULTCC) technology with promising applications in most of the thrust areas of the everyday needs of society as well as in high-performance futuristic concepts.

The firing temperature and co-firing electrode usage classify multilayer glass–ceramic/ceramic composite substrates into three technologies: HTCC (1000–1600°C), LTCC (700–960°C) and ULTCC (<700°C). HTCC enables non-replaceable applications in hermetically sealed ceramic packages. LTCC/ULTCC technologies are inexpensive in terms of fabrication costs and offer a simple process that enables progress in miniaturization and the integration of advances in substrates and packages by combining functional layers and passive electronic components in one multilayer co-sinterable module. Udovic *et al.* (2001) reported the very first materials composition (tellurates) sinterable at below 700°C and later on in 2010 materials compositions were reported under the ULTCC label (Valant and Suvorov, 2001; Udovic *et al.*, 2001; Sebastian *et al.*, 2016; Yu *et al.*, 2015). Since then around 230 material compositions have been reported in this category. In 2017, Chen *et al.* (2017) developed a new tape casting slurry system with co-firability at 450°C feasible for ULTCC multilayer packaging applications. Thereafter, in subsequent years in 2017–2019, two research results were reported by Varghese *et al.* (2018, 2019) on ULTCC microwave and functional substrates co-firable at 400°C and 450°C, respectively, and by Joseph *et al.* (2019) on binder burnout and carbon emission in ULTCC tape casting compositions. In parallel with the ULTCC research, hydrothermal assisted cold sintering/upside down/room temperature ceramics/composites were opening up more and more research in substrate technology. Kähäri *et al.* (2014) reported the very first room temperature sintering process by moistening water-soluble Li_2MoO_4 with deionized water together with a uniaxial compaction pressure of 130 MPa and post-processing sintering at 120°C. Later on in 2016, Guo *et al.*, reported research on a cold sintering process with systematic studies such as the integration of nanotechnology and cold sintering processes (CSP) (Guo *et al.*, 2016a,b,c,d,e,f). They used water as a transient solvent for many of the compositions reported. Currently, many kinds of research are growing in this area for further development in device-level integration and performance studies. CSP may be applied to a very diverse range of materials such as oxides, carbonates, bromides, fluorides, chlorides and phosphates.

Tape Casting and Post-Processing

Tape casting is a casting process utilized for the manufacture of thin ceramic tapes in the thickness range of 5–500 µm from a ceramic slurry. The ceramic slurry processing consists of a series of steps such as distribution of the casting slurry on a flat carrier film and drying it using doctor blade casting technology. Fig. 1 depicts the casting flow and schematic representation of the doctor blade tape casting process. The ingredients included in the tape casting slurries are ceramics/glass–ceramic/ceramic composite powders, solvents, dispersants, plasticizers, homogenizers and binders. The tape casting schematic depicts various components such as a slurry reservoir, doctor blade and carrier film, casting direction and base substrate, followed by processes such as tape drying, peeling, lamination, etc. (Mistler and Twiname, 2000).

The laboratory tape casting process in which slurry is continuously cast on a carrier film, is represented in the schematic in Fig. 1. A mechanically and structurally stable flexible tape is produced based on the careful optimization of the slurry during different stages of the casting process. The casting stages include filler, dispersant and solvent to start with as the first step. Then, after 30 min of mixing, the plasticizers are added followed by the homogenizer and continuous milling for 12 h. The second stage is the addition of the binder to the resultant slurry together with excess solvent and continuous mixing for the next 12 h. The poured final slurry is de-aired under vacuum of 10,000 Pa for 5 min; although the duration mostly depends on the batch size of slurry for casting. Tape casting batching may differ based on surface area and particle size of the initial filler and the selection of solvents, binders, plasticizers, etc. It is better to check the viscosity of the slurry by using the spindle and cup method at 20 rpm to ensure quality control. There is a standard process in tape casting for quality control of the tape casting slurry which includes viscosity and solid loading of the final slurry, particle size distribution and sedimentation analysis. The viscosity and solid loading of the slurry checks are needed for every batch of casting slurry while the particle size and sedimentation analysis are done for the

Fig. 1 The casting flow and schematic representation of the doctor blade tape casting process. Drawn by Jobin Varghese.

initial inorganic fillers and organic composition selection process. Most of the tape casting slurries show a pseudoplastic nature in viscosity measurements; that is the viscosity decreases with increase in shear rate (Mistler and Twinaime, 2000). Wonisch *et al.* (2011) reported theoretical studies on the tape casting slurry as a non-Newtonian fluid which are in the form of a continuity equation and momentum conservation equations, as shown in Eqs. (1) and (2).

$$\rho \left(\frac{\partial u}{\partial t} + u \cdot \nabla u \right) = -\nabla p + \nabla \cdot T + F \quad (1)$$

$$\frac{\partial \rho}{\partial t} = \nabla \cdot (\rho u) = 0 \quad (2)$$

where ρ is the density of slurry, u is the velocity of fluid flow, p is a stress tensor and F represents the external force. There are also several modeling approaches based on analytical and numerical approaches and these are also reported to explain the fluid flow in the tape casting process.

Finally, the resultant slurry is ready to cast. Casting is done on a silicone-coated Mylar film in a continuous tape casting setup as shown in the schematics (Fig. 1). The doctor blade gap setting and casting speed are determined based on the tape thickness required in the product. The most commonly used tape-casting solvents, binder, dispersant and plasticizers are listed in Table 1 (Mistler and Twinaime, 2000).

The selection of the inorganic powder is the first step in the preparation of the tape casting slurry. This is followed by binder and solvent selection. The binder must be dissolved in the selected solvent and the plasticizer is selected based on the choice of binder and solvent. Multiple solvent systems can also be used for the casting slurry preparation, which have the added benefit of dissolving various organics and polymers simultaneously. This provides a wider choice of different varieties of plasticizers, binder and dispersant combinations for slurry preparation. Most manufacturers prefer organic solvent-based tape casting which has a faster drying rate in comparison with aqueous casting. However, aqueous-based casting is a more environmentally friendly casting method compared to organic casting (Hotza and Greil, 1995). The drying of the cast tape is an essential stage in tape casting. Usually, an airflow of $>3.1 \text{ m}^3/\text{h}$ leads to extreme skinning on the tape (Mistler and Twinaime, 2000). Other factors such as solvent concentration, solid loading, type and concentration of binder, temperature of the drying air and thickness of the cast layer are also of concern in the drying stages (Mistler and Twinaime, 2000).

Shrinkage in drying, binder burnout and co-firing/sintering are also crucial for multilayer glass–ceramic/composite substrates. Yu *et al.* (1993) report an exciting study on the evolution of residual carbon in polyvinyl butyral (PVB) and polypropylene carbonates (PPC) on aluminum nitride (Y_2O_3 as sintering aid) tape in air and in a nitrogen atmosphere (Ym *et al.*, 1993). In these studies, the sintering temperature was $1800^\circ\text{C}/1 \text{ h}$ with binder burnout carried out at 550 and 500°C in nitrogen and air atmosphere respectively. The chapter reported on the ALN substrate fabrication in the HTCC range together with the effect of sintering on binder burnout, microstructure and thermal conductivity of the product. The typical post-processing stages after tape casting and drying are punching, via filling, conductor printing, stacking/lamination, pressing and co-firing. Punching is the process of making vias; each layer has a different via size and location based on the design. The via size depends on the thickness of the green tape: in general most manufacturers prefer a 1:1 ratio. Via filling is the process in which each layer of green tape is printed with the conductor pattern. Finally, the layers are stacked, pressed and co-fired to make electronic packages. Table 2 represents the commonly used electrode metals suitable for HTCC, LTCC and ULTCC technology with their conductivity and firing temperature.

Table 1 Commonly used tape casting slurry ingredients

<i>Solvents</i>	<i>Binder</i>	<i>Plasticizers</i>	<i>Dispersant</i>
Xylenes	Polyvinyl alcohol	(poly) Propylene glycols	Menhaden fish oil
Methyl ethyl ketone (MEK)	Polyvinyl butyral	(poly) Ethylene glycols	Polyvinyl butyral
Toluene	Cellulose acetate-Butyrate	Butyl benzyl phthalates	Phosphate ester
1,1,1 trichloroethane (TCE)	Polyacrylate esters	Dimethyl phthalates	Ethoxylate
Acetone	Polypropylene carbonates	Glycerin	Aliphatic hydrocarbons
Ethanol	Polytetrafluoroethylene	Butyl stearate	Lanolin fatty acids
Cyclohexanone	Polyurethane	Dioctyl phthalate	Linoleic acid
Butanol	Ethyl cellulose	Mixed esters phthalates	Polyisobutylene
Isopropanol	Methyl cellulose	Propylene carbonates	Polyethylene glycol
Nitropropane	Vinyl chloride acetate	Tricresyl phosphate	Sodium sulfosuccinates
Water	Polyvinyl chloride	Triethylene glycols	2-amino – 2-methyl – 1-propanol

Note: Mistler, R.E., Twinnage, E.R., 2000. Tape Casting: Theory and Practice. Ohio: The American Ceramic Society.

Table 2 Electrode metals with conductivity and firing temperature suitable for HTCC, LTCC and ULTCC applications

<i>Electrode materials</i>	<i>Applications</i>	<i>Conductivity (S/m)</i>	<i>Melting temperature (°C)</i>
Mo	HTCC	1.87×10^7	2623
W	HTCC	1.89×10^7	3422
Pt	HTCC	9.52×10^6	1768
Pd	HTCC	9.48×10^6	1554
Cu	HTCC	5.95×10^7	1083
Au	HTCC	4.51×10^7	1064
Ag	LTCC	6.30×10^7	961
Al	ULTCC	3.77×10^7	660

However, direct metal electrodes usage is limited by the application and by their co-firability with ceramics/glass–ceramics/composites. This has prompted the introduction of a better solution as composite for co-firing electrodes with better conductivity for the applications. In addition to conductivity, the adhesion between ceramic and metal electrodes, the coefficient of thermal expansion matching with that of the substrate materials or tapes and post processes such as binder burnout, shrinkage and soldering were also under consideration for a multilayer chip (MLC) electrode development process. Hence, additives such as metal alloys and low melting point conductive glasses, ceramics and metals were also considered in additive manufacturing for the preparation of conducting electrodes. As an example, some of the commercially available printable electrode pastes for multi-layer ceramic chip applications are listed in [Table 3](#). It represents some of the commercial electrode materials at various firing ranges with their usages based on ESL and Dupont products (See the web link). However, there are many companies manufacturing various electrode pastes for co-firing. The electrode pastes, which are listed below between the firing temperatures 850–980°C, are suitable for LTCC applications. The electrodes reported at less than 660°C are suitable for ULTCC applications. The electrodes with firing temperature above 1000°C are suitable for HTCC applications.

The electrode compactability also depended on many factors such as the CTE requirements, conductivity requirements, final fired thickness, surface finish of base ceramics or tapes, solderability and adhesion after firing. Typical usages of conductor electrodes in MLC (HTCC, LTCC and ULTCC) are as automotive sensors, oxygen sensors, fuel cells, SOFC (solid oxide fuel cells), solid oxide electrolyzer, SOEC (solid oxide electrolyzer cells), oxygen sensors, chemical sensors, temperature sensors, conical/planar oxygen sensors, chip resistors, SMD capacitor termination and resistance heating. Conventional tape casting and post-processing methods develop the HTCC, LTCC and ULTCC tapes but tape ingredients are varied based on processing temperatures, applications and electrode materials.

High Temperature Co-Fired Ceramic Substrates (HTCC)

HTCC is a well-known choice for hermetic packaging based on its electrical properties, high mechanical stability and good thermal conductivity. The HTCC temperature ranges from well above 1000°C to around 1600°C or more. HTCC utilizes both water-based and organic solvent systems for tape casting. The most common HTCC materials are oxides, nitrides, carbides and borides ([Sebastian and Jantunen, 2017](#)). Al_2O_3 is the most popular material for multilayer packages and substrates due to its performance consistency and continuous usage and production for years with an excellent record of success. However, other oxide materials have also been reported with claims of properties distinct from those of alumina. Most of the commercial production of HTCC tapes and materials meets the needs set by the environmental requirements such as freedom from lead, cadmium, mercury,

Table 3 Some examples of commercial electrode pastes in ESL and Dupont with materials, firing temperatures and purposes (See ESL and Dupont Webpage)

Suppliers	Codes	Materials	Firing temperature (°C) & purpose
ESL	8886-A	Alloyed gold paste (fritless)	850/1 h, ^a < 30 mΩ/sq, suitable for glazed substrates, 1–3 μm Au film
ESL	8884-G	Gold paste #	850–980/1 h, ^a 2–5 mΩ/sq with 12.5 μm fired thickness, Suitable for 96% alumina substrate
ESL	8835 (520C)	Fritted gold paste #	520/15 min, ^a 5 mΩ/sq with 10–15 μm fired thickness, suitable for LTCC, ULTCC, Al ₂ O ₃ , borosilicate, glass, soda-lime, PZT, piezo
ESL	5542	Fritless Pt conductor #	950–1300/15 min, ^a < 100 mΩ/sq with 3–7 μm fired thickness, Suitable for LTCC and HTCC
ESL	2170-A	Tungsten paste	1500–1650°C, 12.5–25 μm emulsion thickness, suitable of HTCC co-firing
ESL	9595-A	Ag/Pd	600–930/12 min, ^a 10 mΩ/sq with fired thickness of 10–15 μm, suitable for post fired ceramics
ESL	9562-G	Pt/Ag/Pd paste #	850–930/30 min, < 4 mΩ/sq with fired thickness of 12.5 μm, suitable for post fired ceramic such as Al ₂ O ₃ , AlN, etc.
ESL	599-E	Cermet Ag conductor	400–550/15 min, ^a 3–6 mΩ/sq with fired thickness of 12.5 μm, suitable for ULTCC and post fired applications
ESL	5051	Metallo-organic platinum paste #	850/12 min, ^a 3–4 mΩ/sq with fired thickness of 0.15–0.25 μm, suitable for post fired ceramics
Dupont	1187	Platable Ag paste #	800/10 min, suitable for multilayer ceramic chip applications
Dupont	4999	Solderable Ag/Pd paste #	710–750/10 min, suitable for multilayer capacitors
Dupont	5426	Ag/Pd paste	850/30 min, suitable for co-firable and chip resistors
Dupont	4899	Solderable Ag paste #	850/40 min, suitable for multilayer capacitors
Dupont	5402S	Platable Ag paste	600–620/30 min, suitable for platable C2 edge termination for chip resistors
Dupont	4933D	Ag/Pd/Pt paste #	710–780/40 min, suitable for ceramic capacitor bodies

Note: Auerkari, P., 1996. Mechanical and physical properties of engineering alumina ceramics. Tirronen, K. (Ed.), Technical Research Centre of Finland, VTT Tiedotteita-Meddelanden-Research Notes, vol. 1792, pp. 1–26. Espoo: Julkaisija-Utgivare-Publisher.

hexavalent chromium, nickel, polybrominated biphenyls, polybrominated diphenyl ether, etc. Those materials/substrates comply with controlled RoHS (Restriction of Hazardous Substances) production.

Oxide HTCCs

Alumina is available in the market in different grades for specific applications based on purity (90%–99%). It offers high strength, good thermal conductivity, hermetic, excellent electrical properties and the lowest cost of production. In some of the commercial HTCC Al₂O₃ green tapes are used with a sintering aid of 4%–8% in order to benefit from the advantages of corrosion resistance, high-temperature resistance, long life, good thermal conductivity and faster thermal compensation. The majority of HTCC production is with either black or white alumina. The material properties of the different grades of Al₂O₃ available are listed in [Table 4](#) based on Auerkari's review report in 1996 (Auerkari, 1996). Their manufacturing temperature varies between 1500–1900°C. The difference in the purity grades are due to some alloying agents or sintering aids based on applications.

In addition to alumina, BeO may be considered for multilayer packaging applications, initially because of its excellent thermal conductivity (250–330 W/mK). However, due to its disadvantages in processing and co-firing other alternative materials are also under consideration for multilayer structures. [Fig. 2](#) presents pictures of some examples of HTCC products as an aid to understanding, as presented in the Adtech Ceramics Company webpages. The customary HTCC products are amplifier housings, ceramic/metal packages, crystal packages, oscillator/SAW packages, high-frequency feedthroughs, hybrid packages, multi-chip modules, optical packages and sensor

Fig. 2 HTCC products presented in the Adtech Ceramics Company webpages. Adapted from the website <http://www.adtechceramics.com/products/htcc>.

packages. ZrSiO_4 is another important HTCC microwave substrate sinterable at 1600°C , which is reported to have a low permittivity ($\epsilon_r = 8\text{--}9.5$ at 5 GHz), low dielectric loss ($\tan \delta = 0.0003\text{--}0.0005$ at 5 GHz), moderate thermal conductivity ($\text{TC} = 14\text{--}15 \text{ W/mK}$) and an ultra-low thermal expansion coefficient ($\text{CTE} = \pm 2 \text{ ppm}/^\circ\text{C}$) (Sebastian and Jantunen, 2017). Similarly, a $0.83\text{ZnAl}_2\text{O}_4\text{--}0.17\text{TiO}_2$ based HTCC substrate is sinterable at 1500°C with a relative permittivity of 9.6 at 5 GHz, dielectric loss of 0.00084 at 5 GHz, thermal conductivity of 31.3 W/mK and CTE of $6.59 \text{ ppm}/^\circ\text{C}$ (Roshni et al., 2017). These microwave HTCC substrates are feasible for high-frequency applications. An attempt to produce a HTCC cordierite-glass substrate (at $1150^\circ\text{C}/2 \text{ h}$) is also in the literature with a low permittivity of 5 and a dielectric loss of 0.002 at 1 MHz (Mei et al., 2006).

Zirconia is another well-known material used for HTCC applications such as oxygen sensors for the automotive industry, fuel cell membranes and structural and biomedical applications. It has a high O_2 diffusivity and high toughness and strength. ZrO_2 has better optical properties than alumina, which makes it feasible for optical device applications. The high temperature stable cubic phase is satisfies for many applications due to its very high melting point of about 2370°C and crystallographic transformation from monoclinic to tetragonal at about 1170°C and from tetragonal to cubic at about 2370°C . (Prakasam et al., 2018). Yttria stabilized cubic zirconia is well known for many applications such as HTCC pressure sensors, solid oxide fuel cells and gas pumps for removing trace oxygen from gases, and its usage is more environmentally friendly due to its oxygen ion conductivity and stability in both oxidizing and reducing atmospheres. Specifically, Zr_2O with 8 mol% of Y_2O_3 has a conductivity of 0.10 S/cm at 1000°C and $3 \times 10^{-5} \text{ S/cm}$ at 400°C with an activation energy of 96 kJ/mol . Moreover, Piticescu et al. (2005) reported a zirconia pressure sensor from hydrothermally synthesized nanoscale 3.5 mol% Y_2O_3 doped ZrO_2 ceramic for use as a HTCC pressure sensor with superior mechanical stability together with high-pressure sensitivity and thermal stability. Schafbauer et al., reported testing another material starting from tape casting for the SOFCs anode support followed by a fuel cell prepared by screen printing and sintering of functional layers such as electrolyte, cathode and current collector layers. The detailed SOFCs workflow is presented in Fig. 3 based on SOFC's reported (Schafbauer et al., 2014; Snijkers et al., 2004).

For further explanation, we will briefly describe the SOFC manufacturing process from tape to device (Schafbauer et al., 2014). The SOFC's manufacturing steps include the mixing of NiO ceramic powder with fully stabilized Zr_2O with 8 mol% of Y_2O_3 (8YSZ) in the weight ratio of 60:40 as the tape casting filler with organic slurry components for the initial green tape preparation. The anode and electrolyte layer are screen-printed on the top of the green tape. The anode layer used for the present SOFC's composition is a more elegant NiO and 8YSZ screen printable paste in the same weight ratio of 60:40. Likewise, the electrolyte layer paste consists of only fine 8YSZ. Both layers have a green thickness of about $10 \mu\text{m}$. After drying the screen-printed layers, tape and screen-printed laminate are co-fired at 1400°C under air atmosphere. The sintered partial cell undergoes various reliability tests such as sintering shrinkages, curvature, electrolyte layer gas tightness and so on. Screen-printing of the cathode layer and current collector layer and its post-firing comprise the next step in the cell manufacture. The cathode paste consists of $\text{La}_{0.65}\text{Sr}_{0.3}\text{MnO}_{3-\delta}$ (LSM) and 8YSZ in the weight ratio of 50:50. On the top of the double-layer cathode. LSM paste with same stoichiometry is screen-printed as the current collector layer. Finally post-firing is performed at 1100°C for

Fig. 3 Schematic representation of the detailed workflow of the SOFCs by Schafbauer *et al.* Redraw by Jobin Varghese based on Schafbauer, W., Menzler, H., Buchkremer, H.P., 2014. Tape casting of anode supports for solid oxide fuel cells at Forschungszentrum Jülich. *International Journal of Applied Ceramic Technology* 11, 125–135.

3 h. The post fired thickness of the cathode is about 15 μm and the current collector layer is about 50 μm for the manufactured SOFCs. Another intermediate temperature solid oxide fuel cell (IT-SOFCs) electrolyte material is lanthanum apatite. Santacruz *et al.* (2011) reported $\text{La}_{10}\text{AlSi}_5\text{O}_{26.5}$ ceramic tape casting sintered at 1650°C/10 h to have feasibility in future IT-SOFCs. However, research in this area is progressing for a cost-effective method of fabrication such as electrolyte plate, 3D printed electrolytes, alternate electrolyte or thin-film electrolyte with better performance for future energy needs (Wang *et al.*, 2019a,b; Feng *et al.*, 2019; Zhou *et al.*, 2019; Liu and Liu, 2019).

Sahner *et al.*, reported in 2005 an SrAl_2O_3 based HTCC gas sensor. In this study, they used SrAl_2O_3 as the HTCC substrate instead of the more commonly used alumina or zirconia. The advantages of SrAl_2O_3 over conventional alumina-based sensors is that it prevents the interaction between the gas-sensitive thick film and the substrate. Additionally, a hydrocarbon-sensing layer of strontium titanate ferrite ($\text{SrTi}_{0.8}\text{Fe}_{0.2}\text{O}_{3-\delta}$) is post fired for gas sensor applications. Hence, the use of an additional diffusion barrier can be omitted from the conventional sensor design. In this study, SrAl_2O_3 is prepared by the conventional solid-state ceramic route with a calcination temperature of 1200°C and the laminated tape is sintered at 1400°C (Sahner *et al.*, 2005). Many more research investigations are in progress in HTCC for specific applications such as sensors for toxic contamination removal, membranes for biofuel production and antimicrobial packaging applications, where high operational stability is required (Ritter *et al.*, 2017; Song *et al.*, 2017; Luo *et al.*, 2017; Huang *et al.*, 2013).

Nitride HTCCs

Due to their excellent thermal conductivity (160 W/mK) and matching coefficient of thermal expansion compared to that of Si, HTCC AlN substrate/packages are utilized for many high heat dissipation and chip applications. Usually, Y_2O_3 ceramic is used as a sintering aid for HTCC AlN production. The sintering temperature (1400–1830°C or above) and sintering conditions of HTCC AlN may be varied to obtain maximum thermal conductivity for the applications (Joedecke *et al.*, 2009; Ym *et al.*, 1993). In general, AlN tape formulation is done with a water-free system because of its highly reactive nature with water. However, some attempts have been made for aqueous tape casting of AlN with hydrolysis inhibitors and anti-hydrolysis protective agents (Luo *et al.*, 2004; Olhero and Ferreira, 2005). In 2017, Shang *et al.* (2017) reported a new method of tape casting for AlN HTCC using gel tape casting and sintering at 1840°C in a N_2 atmosphere and they obtained a thermal conductivity of 161 W/mK. Luo *et al.* investigated the comparison of aqueous and non-aqueous tape casting of AlN substrates. The results showed that the final thermal properties of both methods did not differ much; both sintered at 1850°C/3 h. The residual carbon content was lower in the aqueous compared to the non-aqueous based HTCC AlN (Luo *et al.*, 2005). Another nitride family of materials reported for HTCC substrate applications is Si_3N_4 because of its thermal and mechanical properties. The advantages of the Si_3N_4 substrate over AlN is that it can be manufactured much thinner than AlN (Bitterlich and Heinrich, 2002). Also, the reliability of these materials has been well studied and proven by many applications (Das and Curlee, 1992; Yokota and Ibukiya, 2001). The reactivity with water is similar to that of AlN and produces an oxidized surface on reaction with water. The most common sintering aids for Si_3N_4 are Y_2O_3 and Al_2O_3 . Bitterlich and Heinrich reported an aqueous tape casting composition for Si_3N_4 . These studies covered the tape casting, lamination and post-firing of Si_3N_4 HTCC substrates. The HTCC Si_3N_4 comprised 6 wt% Y_2O_3 and 4 wt% Al_2O_3 as the major sintering aids together with other tape casting organics. The tape lamination was done at 14 MPa for 20 s at room temperature. Binder burnout was carried out at 750°C under a nitrogen atmosphere and was followed by sintering done at subsequent sintering dwells at 1100°C and 1800°C, respectively. The sintered HTCC Si_3N_4 substrate had 98% densification and a linear shrinkage of 20%–24% (Bitterlich and Heinrich, 2002).

Carbide HTCCs

The combination of high strength, hardness, creep resistance, thermal shock resistance and oxidation and acid resistance makes carbides important in HTCC applications. HTCC SiC is reported by both the aqueous and non-aqueous based tape casting routes.

Lv *et al.*, reported aqueous-based SiC HTCC tapes and substrates. The most common sintering aids for SiC, Y_2O_3 and Al_2O_3 , were used in these studies. The laminated tape binder was removed at $600^\circ C/1$ h and hot-pressed at $1850^\circ C$ for 30 min at a pressure of 25 MPa in Ar atmosphere. The final HTCC SiC substrates exhibited 98.89% densification and the flexural strength, hardness and toughness were 779.5 ± 39.2 MPa, 21.51 ± 0.70 GPa and 5.54 ± 0.26 MPa $m^{1/2}$, respectively (Lv *et al.*, 2009). Recently, Kim *et al.*, reported the joining of SiC ceramic using SiC tape by hot pressing at 1800 – $1900^\circ C$ under a pressure of 10–20 MPa in Ar atmosphere. The joined layer showed no residual stress near the join with good mechanical properties as expected (Kim *et al.*, 2019). There is also a report on the TiC based aqueous tape casting process by Zhang *et al.* (2001) but they have not studied its sintering and other properties. However, there is studies reported on its sintering behavior, microstructure, mechanical properties by pressure less sintered ultra refractory carbide using conventional powder compaction and sintering route (Silvestroni and Sciti, 2010). Major advancements in research for the carbide family of materials are progressing for ultra-high temperature ceramics (UHTCs). For example, multilayer joining of ultra refractory carbides such as ZrC, HfC and TaC with Ni/Nd/Ni trilayer is bonded by conventional solid state sintering process at multiple stages. While the bonding done with temperature of $1400^\circ C/30$ min (Silvestroni *et al.*, 2012). Recently, Vinci *et al.* (2019) reported the influence on strength of SiC fiber reinforcement in HfC/SiC composite up to $2100^\circ C$. All these researches are done by solid state approach, the results will also influence the future tape casting and firing process of Carbide HTCCs.

Boride HTCCs

Materials such as ZrB_2 , HfB_2 and Mo_2B_5 have been reported for HTCC and UHTC applications. Among these ZrB_2 was investigated by Natividad *et al.*, in 2011 due to its high melting point of $>3000^\circ C$ and low density. In addition, its mechanical and thermal properties were extensively studied for ultra-high temperature ceramics (UHTC) feasible for thermal protection systems in aerospace vehicles (Natividad *et al.*, 2011). As a UHTC material ZrB_2 has many applications such as Hall-Heroult cell cathode for electrochemical processing of aluminum, evaporation boats, crucible for handling molten metals, thermowell tube for steel refining, thermocouple sleeves for high temperature uses, nozzles and plasma electrodes (Bellosi *et al.*, 2006). On the other hand, the tape casting and binder burnout and densification have been studied and reported. In addition, ZrB_2 is utilized as similarly, Mo_2B_5 has been reported as one of the sintering aids used in the HTCC materials composition of $Al_2O_3/TiC/MoSi_2 + Mo_2B_5$ for HTCC multilayer applications (Zhang *et al.*, 1999). In addition ZrB_2 is also reinforced in ternary matrix composite due to its high melting point, hardness, excellent corrosion resistance, thermal shock resistance, high electrical and thermal conductivity (Sciti *et al.*, 2004; Guo and Kagawa, 2012). Moreover, the reinforcement of ZrB_2 in SiC matrix is found to be useful for the manufacturing of igniters and heating elements because of its satisfactory resistivity, positive temperature coefficient of electrical resistance, higher strength and toughness compared to carbides. It has good oxidation resistance up to $1200^\circ C$ (Sciti *et al.*, 2004). The approach of spark plasma sintering of Hf and Zr based borides are also investigated for cost effective production of these borides (Bellosi *et al.*, 2006). Much more research is needed for the tape casting and post-firing stages of this class of materials before real practical applications in HTCC.

Other HTCC Substrates

Several HTCC multilayer ceramics formed by the stacking of layers, or with different chemical compositions and structures, have been investigated. In particular, Al_2O_3/ZrO_2 , Al_2O_3/SiC , Si_3N_4/BN , $Al_2O_3/TiC/MoSi_2 + Mo_2B_5$, Si_3N_4/BN , $Al_2O_3/TiC/MoSi_2 + Mo_2B_5$, $Al_2O_3/MoSi_2$, $3Al_2O_3 \cdot 2SiO_2/ZrO_2$, $SiC/C/SiC$, SiN (dense)/ SiN (porous), SiC /(glass + fiber) are reported to have HTCC multilayer packaging applications (Boch *et al.*, 1986; She *et al.*, 2000; Liu and Hsu, 1996; Zhang *et al.*, 1999; Watanabe *et al.*, 2001; Park *et al.*, 2000; Clegg, 1992; Shigegaki *et al.*, 1996; Cutler *et al.*, 1996). UHTCs (Ultra High-Temperature Ceramics), a new class of materials with melting points above $3000^\circ C$, are borides, carbides and nitrides (Fahrenholtz *et al.*, 2014). These extreme temperature materials can withstand extreme environments, including the effects of temperature, chemical reactivity, mechanical stress, radiation and wear. Some of the materials under this classification are ZrB_2 , HfB_2 , TaC, ZrC, TiN, YrN and HfC. Recently, UHTCs research is focused on next generation ceramic matrix composites for combustion and harsh environments. Some of the results comprise the graphene sheet reinforced ZrB composites, spark plasma sintered Ti_3SiC_2 -carbon fiber composites, ZrB_2 reinforced with 40 vol% C fiber, 5 vol% SiC, 5 vol% $MoSi_2$, $HfSi_2$, WSi_2 composites are in the category of advancement in UHTCs (Zhang and Sanvito, 2019; Lagos *et al.*, 2019; Silvestroni *et al.*, 2019). Much uncertainty is associated with this class of materials in terms of their melting temperature and considerable research is needed in this area to establish UHTCs.

Low Temperature Co-Fired Ceramics Substrates (LTCC)

LTCC is the cost-effective and upgraded version of HTCC with firing temperatures in the range of 700 – $960^\circ C$. Likewise, HTCC conventional tape casting is the processing of LTCC substrates. The lower fabrication temperature is achieved by the additive manufacturing process of low melting point glasses, ceramics or a combination of both. The major applications of LTCC include hybrid circuits, inductors, resistors, transformers, sensors and microsystems. LTCC offers functionality such as high/low

Fig. 4 LTCC composition types updated based on Rabe *et al.*, report in 2005. Redraw by Jobin Varghese based on Rabe, T., Schiller, W.A., Hochheimer, T., Modes, C., Kipka, A., 2005. Zero shrinkage of LTCC by self-constrained sintering. *International Journal of Applied Ceramic Technology* 2, 374–382.

permittivity, low dielectric loss in a single multilayer package and multi-functional features by integration and interconnections. LTCC also offers the highest interconnect density for the fabrication of 3D structures with the integration of passives such as capacitors, resistors and inductors in a single device. The tape casting and co-firing have been discussed previously in detail. Here are described some of the advances in recent research into LTCC substrates and packaging. LTCC materials have been reported with glass or without glass additives based on their co-firability with metal electrodes. In order to lower the sintering temperature many approaches have been reported such as reducing the particle size of the raw materials, chemical synthesis of the raw materials and the addition of low melting point glass/ceramics. Among these methods, low melting point glass addition is conventionally used for the fabrication of LTCC. Sebastian *et al.*, reported a detailed survey of LTCC materials sinterable at 700–950°C based on their microwave dielectric properties and their co-firability with metal electrodes. The survey listed over 1000 materials with different chemical families feasible for microwave applications (Sebastian, 2008; Sebastian and Jantunen, 2008, 2017; Sebastian *et al.*, 2015, 2016). Rabe *et al.*, describes clear LTCC ceramic types based on their raw materials, composition and sintering mechanisms. Fig. 4 presents an updated view of LTCC composition types based on the Rabe *et al.* (2005) reports.

Based on classifications, we here describe two classes: additive-free LTCC and composite LTCC. The sintering mechanisms involved in these categories are the conventional solid-state sintering reaction, reactive/non-reactive liquid phase sintering and crystallization combined with liquid-phase sintering. The subclasses of LTCC are glass-free LTCC, glass bonded ceramics, glass–ceramic composites and glass ceramics.

Additive-Free LTCC

These are the materials which are sinterable at the LTCC fabrication temperature with co-firability with metal electrode materials without any sintering aid or glass materials through additive manufacturing. There are several materials reported for additive-free LTCC but their application is limited because they lack many other required properties such as thermal conductivity, mechanical stability, matching coefficient of thermal expansion to that of electrode materials and other associated packages, temperature coefficient of resonant frequency for operation stability for the microwave substrates at high-frequency applications, durability and so on. In general, low permittivity materials are useful for LTCC microwave substrate applications whereas high permittivity materials are used for capacitive or resonating applications. The signal speed is directly proportional to the square root of the relative permittivity of the substrate and is shown in Eq. (3).

$$t_d = \frac{\sqrt{\epsilon_r}}{c} \quad (3)$$

Where, t_d is the propagation delay, c is the velocity of light and ϵ_r is the relative permittivity of the substrates. Hence, a low relative permittivity substrate is suitable for increasing the signal speed. Additive-free LTCC materials are also required for the

Table 5 Glass free LTCC materials reported with relative permittivity <10 and $Q \times f > 25,000$ GHz

Material	Sintering temperature ($^{\circ}\text{C}$)	Relative permittivity	$Q \times f$ (GHz)	τ_f (ppm/ $^{\circ}\text{C}$)
$\text{Mg}_3(\text{VO}_4)_2$	950	6.4	48,800	– 83
LiMgPO_4	950	6.6	79,100	– 60

BaMoO_4	900	9.0	37,100	– 90
$\text{Mg}_3(\text{VO}_4)_2$	950	9.1	64,100	– 93
$\text{Ca}_5\text{Mg}_4(\text{VO}_4)_6$	800	9.2	53,300	– 50
BaMoO_4	900	9.3	37,200	– 79
$\text{MgCo}_2(\text{VO}_4)_2$	900	9.4	78,900	– 95
LiMgVO_4	700	9.5	34,800	– 146
$\text{Ba}_2\text{V}_2\text{O}_7$	840	9.6	30,300	– 32
BaTeO_3	800	10.0	34,000	– 54
$\text{NaCa}_2\text{Mg}_2\text{V}_3\text{O}_{12}$	915	10.0	50,600	– 47

Note: Sebastian, M.T., Ubic, R., Jantunen, H., 2015. Low-loss dielectric ceramic materials and their properties. *International Materials Reviews* 60, 392–412.

knowledge of the material properties of many advanced applications irrespective of their primary applications potential (Sebastian and Jantunen, 2008, 2017; Sebastian *et al.*, 2015).

As an example, most of the additive-free materials reported are listed in Table 5 with their sintering temperatures and microwave dielectric properties (relative permittivity <10 and $Qf < 30,000$ GHz with measurement above 1 GHz) based on Sebastian *et al.* (2015) review reports. These material families include phosphates, silicates, borates, molybdates, vanadates, tellurate and tungstates. The table is based on low permittivity materials suitable for microwave applications. Specifically, the materials in Table 5 are moderately good for microwave dielectric properties. However, most of the reported materials have a negative temperature coefficient of resonant frequency which limits the resonant frequency stability and hence their feasibility in practical applications. Moreover, mechanical properties, thermal conductivity and coefficient of thermal expansion of these materials should also be under consideration for device level fabrications.

Composite LTCC

A major class of materials reported for LTCC substrate applications is composite materials. The composite materials are prepared by the additive manufacturing process. The process includes sintering aids such as low melting point sintering ceramic oxides/glass/glass–ceramic that are used for the LTCC raw material development. In addition, chemical synthesis and reduction of the initial particle size of the raw materials were also helpful for lowering the sintering temperatures. The sintering aid selection is based on its sintering temperature and raw materials and, in the case of telecommunication applications, on its microwave dielectric properties. For example, a near zero temperature coefficient of resonant frequency of LTCC materials may be tuned by using additives such as TiO_2 (rutile) or CaTiO_3 with a very high positive temperature coefficient of resonant frequency and low dielectric loss. However, the high sintering temperature restricts its use as much as do the additives. The most common sintering aids are low melting point glasses, which allow a devitrified viscous liquid phase during the firing process to enable sintering and densification together with other additives. Al_2O_3 is the most studied material for composite LTCC substrate feasibility. Most of the commercial products also belong to the glass–ceramics group. Alumina is a major part of commercial LTCC products. The majority of LTCC feasible glasses contain Al_2O_3 , SiO_2 , B_2O_3 and MoO_3 as glass networks because of the low thermal expansion and chemical stability of SiO_2 while B_2O_3 and MoO_3 provide low melting point viscous flow. Al_2O_3 can easily form AlO_4 tetrahedron network structure while SiO_4 tetrahedra increase the connectivity, viscosity and T_g as glass network former. Other common glass network modifiers are Li_2O , Na_2O , K_2O , PbO , CaO , SrO , BaO , MgO and ZnO . Some examples of primary,

secondary and ternary glasses suitable for LTCC materials production are 99 Mole% B_2O_3 (softening point $\sim 450^\circ C$), $40B_2O_3$ – $60SiO_2$ (softening point $\sim 820^\circ C$), $50ZnO$ – $50B_2O_3$ (softening point $\sim 610^\circ C$), $30BaO$ – $60B_2O_3$ – $10SiO_2$ (softening point $\sim 627^\circ C$) and $40PbO$ – $40B_2O_3$ – $20SiO_2$ (softening point $\sim 448^\circ C$). These glasses are feasible for LTCC composition because of their low softening point, low permittivity and low dielectric loss, as is required for many applications. Additives such as glass or sintering aids are an effective way of manufacturing LTCC but in most cases they degrade the primary materials properties, such as the thermal, mechanical and electrical properties, and hence careful selection of additives is needed to develop good quality LTCC by the composite approach. Composite LTCC has been available for the last few decades and the technology is a witness of its market growth and production (Sebastian and Jantunen, 2008, 2017; Sebastian *et al.*, 2015).

Recent Advancement in LTCC Substrates

Further advances in LTCC need innovative materials, ceramic processing and the integration of upgrades into process control. One of the major drawbacks of LTCC is the sintering shrinkage that occurs in all directions, x, y and z. Another disadvantage is free sintering loss, which leads to a lack of geometric precision and hence limits the ability to produce large numbers of modules in a single LTCC. In order to compensate for these disadvantages there are a few constrained sintering mechanisms that are utilized in industry. For example, the use of green laminated tape on a sintered substrate, which prevents green tape shrinkage in the lateral direction only; in this case vertical shrinkage occurs. Another approach is a sacrificial layer on top and bottom of the laminated structure and uniaxial pressure applied during the sintering process, which prevents the lateral shrinkage to some extent. In addition, self-constrained approaches are also in the market with special casting processes and modified LTCC tapes with intermediate or separate sintering intervals. Commercial HL2000 (HeraLock) is developed based on a self-constrained sintering mechanism for shrinkage control. Hence, much research is progressing on developing a self-constrained LTCC tape which offers near zero (x, y direction) sintering shrinkages (Rabe *et al.*, 2005). Another study reports the aqueous and non aqueous fabrication of multilayer ZnO varistors for low breakdown voltage and high surge absorption. Various dopants, including Bi_2O_3 , Sb_2O_3 , Co_3O_4 , Mn_3O_4 and Cr_2O_3 are used in this research along with other organic additive for green tape casting and sintering at $900^\circ C$ (Wang *et al.*, 2008). LTCC is one of the technologies which can develop miniaturized integrated packages such as sensor and actuators. Patel *et al.*, reported a miniaturized hot plate for gas sensor applications. The design and fabrication reveal that the developed LTCC hot plate requires only 144 mW to reach a temperature of $250^\circ C$ (Patel *et al.*, 2012). A recent report discusses wet chemical porosification under alkaline conditions in LTCC for reducing the relative permittivity by embedding air in it. The chemical composition of the LTCC is unaltered by the change in the etching parameters and bath temperature which initiate the porosification processes in LTCC tapes in their fired condition (Hajian *et al.*, 2019). In addition, a 60 GHz high gain planar aperture antenna has been recently reported by Zhu *et al.*, using Ferro A6M LTCC tape for 5G applications. The LTCC A6M substrate exhibits a low permittivity of 5.9 and a dielectric loss of 0.0002 in the microwave frequency ranges (Zhu *et al.*, 2019). Microfluidics is another integrated LTCC technology for biomedical applications such as the enzymatic method of urea determination in LTCC microfluidics (Remiszewska *et al.*, 2019). Other applications are, as recently reported, dual band LTCC band pass filters, miniature electrochemical cells, integrated rectangular waveguides and LTCC monolithic microreactors (Pourzadi *et al.*, 2019; Szymanowska *et al.*, 2019; Isapour and Kouki, 2019; Alonso *et al.*, 2019). Studies on millimeter wave LTCC package research are also in progress for 5th and 6th generation telecommunication products.

Ultra-Low Temperature Co-Fired Ceramic Substrates (ULTCC)

The latest upgrade in multilayer technology is ULTCC. The ULTCC fabrication temperature is in the range of 200 – $700^\circ C$ utilizing existing doctor blade tape casting with new casting compositions. It involves two important classes based on its firing temperature and casting composition. ULTCC Category-1 and Category-2 types have firing temperatures of 200 – 400 and 400 – $700^\circ C$, respectively. There are around 250 materials reported in the literature to date which are feasible for ULTCC applications. Among this most reported materials class are molybdates, vanadates, tellurates, tungstates, phosphates, borates and their composites sinterable below $700^\circ C$ (Sebastian *et al.*, 2016; Yu *et al.*, 2015; Zhou *et al.*, 2018). Ag and Al based conducting pastes are currently available in the market for co-firing. From the beginning of 2010 to the present (2020), extensive research has focused on ULTCC worldwide. However, very little research has been done in the field of tape casting and co-firing. Chen *et al.*, in 2017 reported the very first tape casting composition for ULTCC Category 1 & 2 types, later on much more research was carried out for low and high permittivity and low dielectric loss materials using tape casting and co-firing in recent years (2018–2019). Some of them are listed in Table 6. However, there are other reports on ULTCC Category-2 tape casting and co-firing at 645 and $660^\circ C$ with existing LTCC slurry systems by Honkamo *et al.* (2009) and Zhou *et al.* (2010), respectively.

The most suitable compositions for ULTCC tape organics for both category 1 and category 2 have been studied by Varghese *et al.* (2018) and Joseph *et al.* (2019), respectively, in 2018 and 2019. Joseph *et al.* (2019) report a detailed study on binder burnout and residual carbon in ULTCC by tape casting and co-firing of $CuMoO_4$ and $CuMoO_4$ – Ag_2O ULTCC substrates in comparison with commercial LTCC tapes and substrates. Fig. 5 represents the low residual carbon ULTCC tape developed by Joseph *et al.* (2019), in 2019.

The reported tape casting slurry compositions comprise environmentally friendly organics and non-toxic binders and solvents. The cast tape exhibited low residual carbon of $<5\%$ after sintering which is comparable with commercial LTCC tapes. The

Fig. 5 ULTCC tape with low residual carbon emission reported by Joseph *et al.*, in 2019. Our own picture based on ACS copyright, Joseph, N., Varghese, J., Teirikangas, M., Vahera, T., Jantunen, H., 2019. Ultralow-temperature cofired ceramic substrates with low residual carbon for next generation microwave applications. ACS Applied Materials & Interfaces 11, 23798–23807.

developed ULTCC Category 2 materials exhibit excellent microwave dielectric loss in the range of 10^{-5} and 10^{-4} , respectively, at 10 GHz. These ULTCC substrates (CuMoO₄ and CuMoO₄-Ag₂O) are fired at 500 and 650°C. There are other reports on ULTCC substrates of Li₂WO₄ and CaV₂O₆-glass, which belongs to Category-2 with similar casting compositions and show excellent microwave dielectric properties. Varghese *et al.*, reported ULTCC Category 1 sintering of anatase and rutile TiO₂-glass at 400°C with moderately good microwave dielectric properties and near zero thermal shrinkages with an existing casting composition. In addition, they have investigated a ULTCC dual band antenna for their performance evaluation. The advantages of current developments in ULTCC over HTCC and LTCC technology are shown in Fig. 6 (Varghese *et al.*, 2019).

Recently, ULTCC tape laminated on an aluminum heat sink to isolate the substrate was reported. It has the following advantages over conventional thick film printing of the ULTCC tape. The lamination is done in one step firing, there is easy processing of cavities which is beneficial for recessed lighting, and it can produce 3D substrates for higher performing LED modules at lower cost and longer life time (Grabey *et al.*, 2016). Another important research reported on Si-ULTCC anodic bonding at 150°C, 200 V for an MEMS pressure sensor (Chen *et al.*, 2019). Moreover, very recently Hao *et al.*, presented heterogeneous multilayer dielectric ceramics of ULTCC Category-2 by self-constrained sintering. They demonstrated Li₂MoO₄ (LM) and [(Li_{0.5}Bi_{0.5})_xBi_{1–x}][Mo_xV_{1–x}]O₄ $x = 0.098$ (LBMV) tape casting and multilayer lamination and sintering at 600°C. These studies open up research to realize the solid bonding between heterogeneous materials by self-constrained sintering. Furthermore, low and high permittivity integration leads to guided electromagnetic transmission for future devices through ULTCC research (Hao *et al.*, 2020). Hereafter, much more research is needed to establish the ULTCC technology.

Cold Sintered/Upside Down/Room Temperature Ceramic Substrates (CSCC)

The most recent advance in ceramic processing is known as cold sintered co-fired ceramics (CSCC). It is a new approach to the sintering technique for ceramic and ceramic-based composites prepared by water as a transient solvent for densification at

Fig. 6 Representation of the advantages of ULTCC over HTCC and LTCC technologies by Varghese *et al.*, in 2019. Our own picture based on ACS copyright 6, Varghese, J., Ramachandran, P., Sobocinski, M., Vahera, T., Jantunen, H., 2019. ULTCC glass composites based on rutile and anatase with cofiring at 400°C for high frequency applications. ACS Sustainable Chemistry & Engineering 7, 4274–4283.

Fig. 7 Schematic flow chart of cold pressure or temperature assisted sintering process. Drawn by Jobin Varghese based on Maria, J.-P., Kang, X., Floyd, R.D., *et al.*, 2017. Cold sintering, status and prospects. Journal of Materials Research 32, 3205–3218. Guo, J., Floyd, R., Lowum, S., *et al.*, 2019. Cold sintering: Progress, challenges and future opportunities. Annual Review of Materials Research 49, 275–295.

temperatures between room temperature and 200°C. Cold sintering offers the ability for sintering by water-soluble single or mixed metal oxide ceramics such as molybdates, vanadates, tungstates, carbonates, chlorides, sulfates, fluorides, phosphates and borates with applied pressure/temperature. The integration of cold sintering with thermoplastic composites, hydrothermal assisted processes, nanotechnology, flexible-printable electroceramics devices, solid electrolytes and microwave ceramics are well studied and reported (Guo *et al.*, 2016a,b,c; Baker *et al.*, 2016; Berbano *et al.*, 2017; Kähäri *et al.*, 2014). The ferroelectric material process, capacitor material process, ceramic packaging, and semiconductor process, Li-ion cathode, magnetic materials, sputtering targets and piezoelectric materials are the current research and development fields (Guo *et al.*, 2016c,d; Polotai *et al.*, 2005; Guo *et al.*, 2016b,f, 2017, 2019). Maria *et al.*, and Guo *et al.*, reported a detailed review of cold sintering in 2017 and 2019, respectively. They discuss and review the historical background and the standard process, mechanism, applications and future prospects of the cold sintering process (Maria *et al.*, 2017; Guo *et al.*, 2019). A standard spectrum of cold sinterable ceramics includes binary, ternary, quaternary and quinary compounds like MoO_3 , Li_2CO_3 , LiFePO_4 and $\text{LiAl}_{0.5}\text{Ge}_{1.5}(\text{PO}_4)_3$. Fig. 7 represents the schematic flow of the cold pressure or temperature assisted sintering process (Maria *et al.*, 2017; Guo *et al.*, 2019).

The cold sintering process consists of two phases comprising compaction, consolidation, densification and crystallization during cold sintering. The compaction process is the conventional process in which particles are rearranged by sliding, grain boundary creep, etc., with partial extrusion of the liquid phase or temperature/pressure-assisted dissolution and evaporation. Mass

transport and induced nucleation happen in the pressure/temperature sintering process at the final stage of densification. Recently, Wang *et al.* (2019a,b) reported a multilayer ceramic capacitor (MLCCs) based on $(\text{Bi}_{0.95}\text{Li}_{0.05})(\text{V}_{0.9}\text{Mo}_{0.1})\text{O}_4\text{-Na}_2\text{Mo}_2\text{O}_7$ with a relative permittivity of 39, temperature coefficient of capacitance of $\pm 0.01\%$ and $\tan \delta$ of 0.01 at 1 MHz fabricated by the cold sintering process at 150°C . Another work demonstrated metallization integration in co-fired MLCs by the cold sintering process, the metals included Cu, Fe and Al co-fired with ZnO ceramics uniaxially pressed at 200 MPa pressure together with a sintering temperature of $260^\circ\text{C}/1\text{ h}$ (Beauvoir *et al.*, 2019). Nelo *et al.*, report upside down composites using a piezoelectric filler with an aqueous dispersion of lithium molybdate as binder by pressing at 250 MPa and subsequent drying at $120^\circ\text{C}/18\text{ h}$. The composites showed a moderately good voltage constant of $-33\text{ mVm}\cdot\text{N}^{-1}$ in comparison with bulk materials (Nelo *et al.*, 2019). However, there is research needed into the fundamentals and the engineering processes of cold sintering.

Summary

The chapter gives some brief historic aspects of multilayer ceramic substrate technology together with the present status of multilayer glass–ceramic/composite substrates prepared by HTCC, LTCC, ULTCC and the growth of UHTCs and cold sintering/room temperature fabrication/upside-down composite fabrications based on present and recent literature surveys. The markets and industries are in need of advanced materials and processing technology for future generations of devices based on technology demands. In addition to this, environmental and energy concerns are a challenge to the ceramic researchers to full fill future environmentally friendly ceramic utilized for circular economy.

Functional Ceramics through Novel Chemical Approaches

K Kato and Y Torii, National Institute of Advanced Industrial Science and Technology, Nagoya, Japan
G Majumdar, Jadavpur University, Kolkata, India

© 2017 Elsevier Inc. All rights reserved.

Chemical processing is a promising technique for the synthesis of functional ceramic thin films. Functions of ceramic thin films are predominantly determined by their crystal structure, composition, and microstructure. Precise control of these three fundamental factors is a key to developing high performance. Chemical processing via liquid sources, especially, should be focused on because they have many attractive advantages. The molecular structure of the liquid source should be designed and its reactivity optimized for the hydrolysis reaction, photoreaction and combustion, low-temperature crystallization, and the characteristic microstructure achieved in the ceramic thin film. Furthermore, chemical processing is essential for the integration of ceramic thin films into silicon semiconductors. Integration not only enhances each function, but allows the combination of multi-functions and thus provides unique performance.

Chemical Modification for Porous and Nano-Structured TiO₂ Thin Films

Poly(ethylene glycol) (PEG) can be coordinated to a structure formed by the controlled hydrolysis and polycondensation reactions of titanium tetraisopropoxide chelated with diethanolamine. From the resulting chemically modified precursor solution, anatase coatings consisting of nanometer-sized pores and grains with diameters of about 30 nm, and a preferred orientation along c-axis, can be prepared on quartz glass plates by a dip-coating method. In contrast, anatase coatings consisting of submicron-sized pores and randomly oriented grains can be prepared from the solution in which the PEG has been isolated (**Fig. 1**) (Kato *et al.*, 1996b).

The new roles of PEG in chemical processing have been confirmed. The PEG-derived organic compounds remain in a fixed position in the thin film prepared from the chemically modified titanium tetraisopropoxide solution and heated at temperatures as high as 673 K. It is not until the organic compounds decompose to carbon dioxide and the gas leaves the thin film that the nano-structure – consisting of nano-sized pores and anatase crystallites with preferred orientation – develops at 723 K (**Fig. 2**) (Kato and Nihara, 1997).

Fujishima and Honda (1972) reported that photosensitized electrolytic oxidation of water occurs on the surface of TiO₂ (rutile) single crystals. The reaction, the so-called photocatalytic reaction, was studied during the 1990s for potential application to environmental issues such as the purification and treatment of air and water. The photocatalytic reactions occurring on the surface of TiO₂ depend on this process, which starts from the absorption of light and results in photogenerated electrons and holes at the surface. The photocatalytic process is predominantly determined by the fundamental physical properties of TiO₂. Porous and nano-structured TiO₂ thin films have been examined for the photocatalytic decomposition of aqueous acetic acid, a key reaction for the purification and treatment of water. TiO₂ thin films with a thickness of 500 nm show high photocatalytic activity, which means that aqueous acetic acid (6 wt%) is decomposed in 30 min after irradiation performed using a high-pressure mercury lamp (**Fig. 3**) (Kato *et al.*, 1996a).

A photoelectrochemical solar cell based on dye-sensitized nanocrystalline TiO₂ films has been reported (O'Regan and Gratzel, 1991). The nanocrystalline TiO₂ films consisting of nanometer-sized anatase particles have enhanced geometrical surface area and a thickness of 8–12 μm . Thereby, adsorption of a large amount of the sensitizing dye followed by high energy conversion could be attained. In comparison, porous and nano-structured TiO₂ thin films with a thickness of less than 1 μm adsorb relatively large amounts of the dye and show increased photocurrent densities. This suggests that the amount of adsorbed dye could be adjusted

Fig. 2 Transmission electron micrographs of TiO_2 thin films prepared from the chemically modified titanium tetraisopropoxide solution with temperatures (after Kato and Niihara, 1997).

Fig. 3 Photocatalytic activity of TiO_2 thin films with various microstructures: changes in the content of acetic acid with irradiation time.

by controlling both the pore and crystallite sizes and that then even thinner TiO_2 films could show higher performances (Miki *et al.*, 1996).

Hau Ng *et al.* (2010) investigated graphene- TiO_2 nanocomposites synthesized via a solution-based method involving photocatalytic reduction of graphene oxide. Nearly 90% enhancement in the photocurrent was seen as reduced graphene oxide serves as electron collector and transporter. Additionally, the graphene- TiO_2 nanocomposite electrodes exhibited significant activity for the complete photocatalytic decomposition of 2,4-dichlorophenoxyacetic acid (2,4-D). Combined with safe, solution-based synthetic practices, the promising photocurrent and photocatalytic degradation rates provide the framework and motivation for the implementation of graphene- TiO_2 nanocomposites on larger scales. The implementation of graphene- TiO_2 nanocomposites has been shown schematically in the Fig. 4.

Fig. 4 Schematic diagram of the implementation of graphene-TiO₂ nanocomposites.

Fig. 5 Chemistry for the formation of SBT and SBN precursors (after Kato *et al.*, 1997a).

Low-Temperature Processing of Layer-Structured Perovskite Thin Films

Thin films of layer-structured perovskite compounds, such as SrBi₂Ta₂O₉ (SBT), SrBi₂Nb₂O₉ (SBN), and SrBi₂(Nb, Ta)₂O₉ (SBNT) are promising materials for nonvolatile ferroelectric memory applications due to their excellent ferroelectric properties – especially with respect to fatigue performance (Araujo *et al.*, 1995). The solid solutions SrBi₂M₂O₉ (where M is Ta or Nb), which are known as Aurivillius compounds, consist of a stack of alternating layers of oxygen octahedra (SrM₂O₇)²⁻ in the c-direction. The high spontaneous polarization is parallel to the plane of the layers (in the a-direction) because this direction contains the O–M–O chains that are known to have high capabilities for polarization, as in perovskite ferroelectrics. It is imperative for these compounds that processing temperatures are lowered to those similar to complementary metal oxide semiconductor (CMOS) technology. In addition, degradation of electrical properties is caused by bottom electrode–thin film interface reactions at relatively high temperatures.

Precursors for layer-structured perovskite thin films of SBT, SBN, and SBNT have been prepared by the reaction of a strontium–bismuth double methoxyethoxide and tantalum or niobium methoxyethoxide in methoxyethanol, followed by partial hydrolysis. Several spectroscopic techniques, such as ¹H-NMR, ¹³C-NMR, ⁹³Nb-NMR, and FTIR spectroscopy, can be used to analyze the arrangement of the metals and oxygen in the precursor molecules. The precursors contain Sr–O–M (where M is Ta or Nb) bonds (i.e., a strontium atom is connected to two MO₆ octahedra) and Sr–O–Bi bonds, with a bismuth atom bonded to the oxygen atoms of the MO₆ octahedron.

The arrangement of metal and oxygen atoms is considered similar to the layer-structured perovskite crystal sublattice (Fig. 5). As a result, the sol–gel derived SBT thin films can be crystallized by rapid thermal annealing in an oxygen atmosphere below 550 °C; they exhibit preferred {115} orientation. The crystallinity improves and the crystallite size increases with temperatures of up to 700 °C. In the case of SBN thin films, a low heating rate (2 °C min⁻¹) is necessary to control the crystallographic {115} orientation, whereas a rate of 200 °C s⁻¹ (rapid thermal annealing) produces films that exhibit c-axis orientation. The {115} SBT thin film exhibits improved ferroelectric properties when heated to 700 °C (Kato *et al.*, 1998). A SBT thin film annealed at 700 °C does not show fatigue after 10¹⁰ cycles of switching (Fig. 6).

A film deposited from the complex ethoxide solution, and then calcined at 250 °C in the mixture of water vapor and oxygen flow, contains a relatively smaller amount of the remaining alkoxy groups (Kato, 1998). It therefore crystallizes to SBT via rapid thermal annealing at temperature below 500 °C in an oxygen flow. Crystallinity improves significantly and the microstructure develops up to 650 °C. Remarkable grain growth is observed, particularly in the SBT thin film deposited from the ethanolic solution of the complex ethoxide. Film annealed at 650 °C exhibits saturated P–E hysteresis loop and improved endurance behavior.

Fig. 6 Fatigue behavior of a Pt/SBT/Pt capacitor (after Kato *et al.*, 1997a).

Wang *et al.* (2013) reported a low-cost, solution-based deposition procedure utilizing nanocomposites of graphene and TiO_2 nanoparticles as the electron collection layers in meso-superstructured perovskite solar cells. The graphene nano flakes provide superior charge-collection in the nanocomposites, enabling the entire device to be fabricated at temperatures no higher than 150°C . The solar cells showed remarkable photovoltaic performance with power conversion efficiency up to 15.6%. The work demonstrates that graphene/metal oxide nanocomposites have the potential to contribute significantly toward the development of low-cost solar cells.

You *et al.* (2014) adopted a low-temperature processing technique to attain high-efficiency devices in both rigid and flexible substrates, using device structure substrate/ITO/PEDOT:PSS/ $\text{CH}_3\text{NH}_3\text{PbI}_{3-x}\text{Cl}_x$ /PCBM/Al, where PEDOT:PSS and PCBM are used as hole and electron transport layers, respectively. Mixed halide perovskite, $\text{CH}_3\text{NH}_3\text{PbI}_{3-x}\text{Cl}_x$, was used due to its long carrier lifetime and good electrical properties. All of these layers are solution-processed under 120°C . Based on the proposed device structure, power conversion efficiency (PCE) of 11.5% is obtained in rigid substrates (glass/ITO), and a 9.2% PCE is achieved for a polyethylene terephthalate/ITO flexible substrate.

UV-Processing of Perovskite Solid-Solution Thin Films

Potassium tantalate niobate ($\text{KTa}_x\text{Nb}_{1-x}\text{O}_3$) (KTN) has a perovskite structure, and is a solid solution of potassium tantalate (KTaO_3) and potassium niobate (KNbO_3). The ferroelectric properties of KTN can be controlled by the Ta/Nb ratio, since the Curie temperature of KTN varies almost linearly with the Ta/Nb ratio (Trieblwasser, 1959). KTN has attracted much attention for its potential application in optoelectronics and integrated optics because it has large electrooptic and nonlinear optic effects (Orlowski *et al.*, 1980). The fabrication of a KTN waveguide is one of the key techniques for its application to integrated optics.

KTN thin films have been prepared by the chemical solution deposition method. KTN precursors consist of $\text{K}[\text{Ta}(\text{OC}_2\text{H}_5)_6]$ and $\text{K}[\text{Nb}(\text{OC}_2\text{H}_5)_6]$, with interaction at a molecular level. Perovskite KTN thin films with the desired composition Ta/Nb = 65/35, 50/50, and 35/65 have been synthesized from precursor solutions by the dip-coating method. KTN thin films with {100} preferred orientation have been successfully deposited on $\text{MgO}\{100\}$ and $\text{Pt}\{100\}/\text{MgO}\{100\}$ substrates.

X-ray pole figure measurements show that grains of KTN thin films have a prominent three-dimensional regularity on $\text{MgO}\{100\}$ and $\text{Pt}\{100\}/\text{MgO}\{100\}$ surfaces. The Curie temperatures of KTN films decrease with increasing Ta/Nb ratio. Typical P-E hysteresis loops were observed for the three compositions of KTN thin films on $\text{Pt}\{100\}/\text{MgO}\{100\}$ substrates. The values of remanent polarization (P_r) of KTN thin films increase as the Ta/Nb ratio changes from 65/35 to 35/65 (Fig. 7) (Suzuki *et al.*, 1999a).

UV-processing has been used for the patterning of ceramic films. The ligands should be chosen carefully as the use of large organic ligands degrades the electrical properties of resultant films. Patterned $\text{KTa}_{0.50}\text{Nb}_{0.50}\text{O}_3$ (KTN50) thin films with a {100}-preferred orientation have been successfully crystallized at 700°C on $\text{MgO}\{100\}$ substrates. Both benzoylacetone (BZAC)-modified KTN precursor and 2-ethoxyethanol (EGMEE)-modified KTN precursor films show charge-transfer UV absorption. The decrease in CH and CO absorptions in the IR spectra for the EGMEE-modified precursor is more rapid than that in the BZAC-modified precursor. Perovskite KTN films with a prominent {100} orientation crystallize at 700°C on $\text{MgO}\{100\}$ substrates from both systems.

However, the epitaxy of KTN films from the EGMEE-modified precursor combined with UV treatment is better than that from the BZAC-modified precursor. The optical transmittance of KTN films from the EGMEE-modified precursor shows a better interference fringe than that from the BZAC-modified precursor. UV-treated KTN films on $\text{Pt}\{100\}/\text{MgO}\{100\}$ substrates are derived from the EGMEE-modified precursor reveal the highest dielectric constant and the lowest loss (Fig. 8). According to scanning electron microscopy (SEM) observation, patterned KTN films from the EGMEE-modified precursor have a smooth and pore-free surface (Suzuki *et al.*, 1999b).

Fig. 7 P-E hysteresis curves of KTN films on Pt(100)/MgO(100) substrates at $-180\text{ }^{\circ}\text{C}$: (a) KTN35 film, (b) KTN50 film, (c) KTN65 film.

Fig. 8 Changes in dielectric constant and loss tangent with temperature for KTN50 films crystallized at $700\text{ }^{\circ}\text{C}$ on Pt(100)/MgO(100) substrates: (a) KTN50 films from BZAC-modified precursor with UV irradiation, (b) KTN 50 films from EGME-modified precursor without UV irradiation, and (c) KTN50 films from EGME-modified precursor with UV irradiation.

Taylor (2010) reported the preparation of $(1-x)$ PMN- x PT ceramics with $x=0.28 - 0.32$ in pure phase using a novel chemical solution method. The ceramics displayed better piezoelectric properties compared to those prepared by conventional solid state method. To optimize the ceramic properties, the effect of high temperature poling was investigated, and it was found that poling at high temperature degraded the piezoelectric properties due to an electric field induced phase transition. The same solution method was used to fabricate ceramics of $(1-x)$ PMN- x PT with $x=0.07$ and 0.10 which exhibit their maximum of permittivity near room temperature. A sintering temperature of $1100\text{ }^{\circ}\text{C}/4\text{hrs}$ was required in order to obtain high density, reduce dielectric losses, and increase the dielectric permittivity in order to optimize capacitive performance. The solid solution between $\text{Pb}(\text{Mg}_{1/3}\text{Nb}_{2/3})\text{O}_3$ (PMN) and $\text{Bi}(\text{Zn}_{1/2}\text{Ti}_{1/2})\text{O}_3$ (BZT) was investigated for its structure and dielectric behavior. The addition of BZT to PMN did not change the structure significantly and it remained cubic to the solubility limit of $0.725\text{ PMN}-0.275\text{ BZT}$. The dielectric properties exhibit an increase in frequency and temperature dispersion with increasing BZT content, indicating an increase in relaxor behavior. The $\text{Pb}(\text{Mg}_{1/3}\text{Nb}_{2/3})\text{O}_3\text{-PbTiO}_3\text{-Bi}(\text{Zn}_{1/2}\text{Ti}_{1/2})\text{O}_3$ solid solution was prepared in order to explore its structure, dielectric, ferroelectric, and piezoelectric properties as a function of composition for use in high TC piezoelectric applications. The structure and properties were mapped as a function of composition to establish the ternary phase diagrams of this system for its structure, dielectric, and piezo-/ferroelectric properties.

Conclusion

Chemical modification and processing of different thin films have been discussed. KTN thin films have been prepared by the chemical solution deposition method. UV-processing has been used for the patterning of ceramic films. The epitaxy of KTN films from the EGME-modified precursor combined with UV treatment is better than that from the BZAC-modified precursor. The

optical transmittance of KTN films from the EGMEE-modified precursor shows a better interference fringe than that from the BZAC-modified precursor. Patterned KTN films from the EGMEE-modified precursor have a smooth and pore-free surface.

Overview: Bioceramics and Bioreactive Glasses

Anne Leriche, Polytechnic University Hauts-de-France, Valenciennes, France

Francis Cambier, Belgian Ceramic Research Centre, Mons, Belgium

© 2021 Elsevier Inc. All rights reserved.

The living being is a complex system integrating a large number of functions. Over the course of life, depending on accidents, illnesses, natural wear, etc. some functions deteriorate. Within certain limits, the body can react on its own and restore (sometimes only partially) the affected function. Nevertheless, with the global increase in aging human populations and the desire to maintain essential functions as efficiently as possible, the need for corrective procedures increases.

Among the materials likely to be involved in such procedures are metals, polymers, ceramics and glasses. Ceramics and glasses exhibit extremely varied and exceptional properties that have enabled them to be widely used for over a century in a series of various industrial fields. The use as a material in medicine has particularly accelerated over the past 50 years. From the earliest biomedical applications to date, research has also focused on understanding the relationships between composition, process, structure, texture, microstructure and resulting properties, which has enabled significant advances in terms of clinical performance.

The majority of developments are today found in the replacement or repair of hard tissue (bones, teeth), but not only. On the one hand, procedures such as total hip and knee replacements, bone reconstructions and spinal fusions, resulting from conditions such as articular cartilage degeneration and osteoporosis are today largely used. On the other hand, commercial calcium phosphate composites and glasses for bone regeneration are available, but restricted to applications that require only moderate load bearing abilities. High toughness bioinert materials are used in the articulating couple of artificial joint implants, but they do not induce direct bone/material interfaces or bond. The research is therefore focused on tough and strong materials with the ability to create a biologically relevant interface with bone.

This section of the Encyclopedia of Materials: Technical Ceramics and Glasses is specifically devoted to “*Bioceramics and Bioglasses*”. It includes five subsections:

- A. The first subsection (4 chapters) focuses on the main areas of application: after an introductory chapter describing the different properties of bones and another giving an overview of natural and synthetic bone substitutes, new trends, on the one hand in orthopedics, on the other hand in dentistry are described and discussed.
- B. The second part (5 chapters) focuses on inert bioceramics, it includes description of oxide, non oxide and carbon based materials. The two last chapters deal more precisely with zirconia (Y-TZP) and with zirconia toughened alumina composites (ZTA). Zirconia, which shows extremely favorable properties, has been primarily largely used in orthopedic. However, when the phenomenon of low temperature degradation in the presence of aqueous media was discovered, less sensible alumina-zirconia composites were tested and are now predominantly used in orthopedics, whereas TZP materials are now more and more utilized as crowns and even as implants in dentistry.
- C. The third subsection is devoted to bioreactive ceramics and glasses (7 chapters). The goal of such materials is to induce or simply to allow bone regeneration by providing (through complex mechanisms) a mineral source of calcium and phosphate to the bone/material interfaces. Calcium phosphate composites (hydroxyapatite, beta-TCP and derivatives) as well as bioreactive glasses (containing Ca and P) are restricted to applications that require only moderate load bearing abilities. After a first chapter giving an introduction on phosphate chemistry, it is successively treated: (1) a general overview of apatitic and tricalcic calcium phosphate bioceramics and (2) their applications in biomedical engineering. Ca and P are also key components of bioreactive glass compositions and of course of calcium phosphate cements (2 chapters). The 2 last chapters are focused on the use of the calcium phosphate materials in regenerative medicine and more precisely on the use of scaffolds in the regeneration of bones.
- D. The fourth part of this section aims to illustrate the progress made so far in the context of bone imitation. Most of the material processes, presented in the introductory chapter, play on the architecture and composition of ceramic and glass scaffolds. A chapter is devoted to bioactive and bioresorbable ceramic-polymer composites. The following three chapters deal with the interfaces between bones and biomaterials, either by different surface treatments, or by functionalization of the ceramic, also by projection of biomaterials on the surface of metal devices used in surgery. Another chapter presents the use of mathematical modeling to design suitable scaffolds. Finally, the last chapter illustrates very original approaches to prepare new generation bioceramics allowing an increased cellular response.
- E. The fifth subsection provides an overview of characterization techniques for bioceramics and bioreactive glasses. In four chapters, readers will have complete information on the mechanical testing of bioceramics and bioreactive glasses for both orthopedics and dentistry; a description of in vitro and in vivo tests and their biological evaluation; and finally a discussion on the clinical and biological aspects of the use of zirconia in dentistry.

Bone as a Material: Lessons From Nature

Laura M O'Sullivan and Laoise M McNamara, National University of Ireland Galway, Galway, Ireland

Introduction: Bone Composition

Bone is a composite material made up of an organic phase and a mineral phase (Currey, 1984). The organic phase of bone tissue comprises a matrix formed by the collagen protein, other “non-collagenous” proteins (NCPs), water, lipids and cells, which together represent approximately 35% of the entire bone mass. The mineral phase of bone is mostly comprised of calcium and phosphorous in the form of hydroxyapatite crystals and accounts for 25% of bone volume and 65% of bone mass, and imparts mechanical integrity, compressive strength and hardness to bone tissue and thereby enables the load bearing and resistance to fracture by the skeleton. The quantity and mechanical integrity of each phase, their structural organization and interactions, determine the unique properties of bone.

Collagen

Collagen is the most abundant protein of the organic phase (90%) and forms the underlying matrix and provides a critical role in defining bone shape and structural integrity. This matrix of collagen ultimately provides the structure upon which other proteins and mineral crystals can be anchored (Glimcher, 1959).

The basic structural unit of collagen is tropocollagen, a triple helix molecule composed of three polypeptide strands (alpha chains) twisted together into a right handed coil. Covalent cross-links, comprised of pyridinium and pyrrole proteins, stabilize these collagen fibrils by forming bridges between non-helical regions and helical regions of adjacent collagen molecules. A collagen fiber is characterized by a staggered arrangement of cross-linked tropocollagen molecules, see Fig. 1. Within bone tissue these collagen fibers are organized into concentric layers known as lamellae, within which they are arranged parallel to one another. Fibrils located in adjacent lamellae are aligned at an angle of up to 90° relative to each other. This complex organization of tropocollagen molecules at the nanoscale and lamellae of collagen fibers at the microscale, determine the tensile strength, elasticity and toughness of bone (Ascenzi and Bonucci, 1976). There are approximately 28 different forms of collagen, each named with Roman numerals (I-XXVII), which are characterized by the arrangement of the tropocollagen molecules and fibrils in their collagen structure. For instance, collagen type I has a heterotrimeric structure with one polypeptide chain that is not identical to the others whereas collagen type III has a homometric triple helix structure, which is made up of three identical alpha chains. Approximately 95% of the collagen in bone is type I but type III, IV and VI are also present.

Mineral

The basic unit of bone mineral are small crystals of hydroxyapatite ($\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$), which are formed by osteoblasts cells, when calcium and phosphate ions bind to one another in the presence of NCPs, such as osteopontin and bone sialoprotein,

during a process called nucleation. This nucleated hydroxyapatite crystal gradually grows in size as further calcium and phosphate ions are added to the crystal cluster overtime (Cowin, 2001). A series of gaps and channels exist within the collagen matrix providing space for deposition and growth of plate like-crystals, which are orientated parallel to the collagen fibers in the underlying matrix, see Fig. 2(A). The crystal size and distribution are dependent on the matrix dimensions and unoccupied voids throughout the structure (Cowin, 2001; Hassenkam *et al.*, 2004; Paschalis *et al.*, 1996). Studies using various microscopy techniques have observed heterogeneous mineral distribution in trabecular tissue, which is partly explained by the adaptive bone remodeling process (Brennan *et al.*, 2011a; Camacho *et al.*, 1999; Derx and Birkenhager-Frenkel, 1995; Gadeleta *et al.*, 2000; Obrant and Odselius, 1984; Roschger *et al.*, 2008). In the case of trabecular bone, this remodeling occurs at the trabecular surface ($\sim 25 \mu\text{m}$) where the tissue often has low mineral content, as remodeling does not allow adequate time for complete tissue mineralization. The tissue at the center of the trabecula is not affected by remodeling and the tissue mineral content increases overtime. This results in a heterogeneous mineral distribution throughout trabecular tissue, see Fig. 2(B).

Binding of a non-collagenous protein, called osteocalcin (see Section “Non-collagenous proteins and cells” below), to the matrix surface can prevent crystal formation through blocking nucleation sites (Boskey *et al.*, 1993; Poundarik *et al.*, 2018). The rate of mineralization can also be affected by alterations in the local ionic concentration. These processes regulate the development of inorganic mineral crystals throughout bone tissue (Cowin, 2001). The degree of bone mineral is substantially different between distinct anatomical sites and between different people, especially gender and age-dependent differences have been reported. Bone mineral content is typically increasing with age, until 60 years of age, when the mineral content begins to decrease in both men and women (Currey *et al.*, 1996), altering the stiffness and strength of bone tissue. Conversely, bone tissue with high mineral content is more brittle and susceptible to more extensive crack propagation, which in turn dramatically reduces bone toughness and impact strength. Genetic disorders which impact the organization of the underlying collagen structure can affect the mineral composition in bone tissue.

Non-Collagenous Proteins and Cells

Non-collagenous proteins make up 10% of the bone organic phase and have multiple functions in the bone extracellular matrix (ECM), which affect bone matrix formation, matrix quality and mechanical properties. These non-collagenous proteins bind adjacent collagen fibrils in mineralized tissue, via Ca^{2+} mediated bonds. They undergo reversible rupture and have been proposed to act as “sacrificial bonds” (Fig. 3), whereby the mechanical energy dissipated due to rupture prevents stresses from reaching levels that could delaminate the bone matrix and therefore contributes to bone fracture toughness (Fantner *et al.*, 2007, 2005, 2006; Hansma *et al.*, 2005; Thurner *et al.*, 2007, 2009).

Osteocalcin (OC) is the most abundant NCP in bone tissue and is known to regulate the growth of bone mineral crystals, without impairing the mineralization process involved in initial bone formation. Osteocalcin is required for bone mineral maturation (Boskey *et al.*, 1998) and reduced osteocalcin levels may contribute to decreases in bone mineral content and stiffness (Berezovska *et al.*, 2019). Osteonectin, a protein found predominantly in trabecular bone, is believed to facilitate binding between bone mineral and the collagen matrix, and is proposed to act to commence the active mineralization of bone tissue (Termine *et al.*, 1981). Osteonectin deficiency results in severely depleted trabecular bone (Ducy *et al.*, 1996), while cortical bone has compromised matrix quality (Boskey *et al.*, 2003) and decreased strength and stiffness in 3-point bending (Beamer *et al.*, 1996; Delany *et al.*, 2000). Fibronectin (FN) is a glycoprotein which is critical to bone formation and function, as it is expressed at high levels by bone forming cells (Jia *et al.*, 2002; Robey and Termine, 1985; Young, 2003). Studies suggest that FN is essential for collagen type I accumulation (Dallas *et al.*, 2005; McDonald, 1988; Sottile and Hocking, 2002) and therefore may have an impact on the quality and organization of bone collagen matrix (Singh *et al.*, 2010). Thrombospondin-2 (TSP2) has been found to play an important

Fig. 3 High resolution Scanning Electron Micrographs (A & B) and AFM (C) show NCPs resisting fracture in bone. Schematic (D) represents the two adjacent mineralized collagen fibers successfully bind to one another via NCPs and (E) represents the NCPs resisting the formation of microcracking (open access material under the “Creative Common License CC BY-NC-SA 4.0”, see more detail at: <http://creativecommons.org/licenses/by-nc-sa/4.0/>). Reproduced from Hansma, P.K., Fantner, G.E., Kindt, J.H., *et al.*, 2005. Sacrificial bonds in the interfibrillar matrix of bone. *Journal of Musculoskeletal & Neuronal Interactions* 5, 313–315.

role in the development of the collagen matrix (Alford *et al.*, 2013; Manley *et al.*, 2015) and therefore has an impact on the mechanical integrity of bone tissue. In fact, femoral cortical bone from TSP2-deficient mice consisted of a defective organic matrix, which exhibited brittle material behavior through reduced post-yield ductility (Manley *et al.*, 2015). Recent studies have demonstrated that Osteopontin (OPN), bone sialoprotein (BSP) and dentrin matrix protein-I (DMP1) proteins, have a direct influence on the mechanical properties of bone. In fact, OPN deficiency has been shown to compromise the resistance to crack propagation, decrease the matrix elastic modulus and increase calcium variability in cortical bone (Turner *et al.*, 2010).

Bone tissue is created and its strength is sustained by a number of bone cells, which comprise approximately 5% of the tissue mass. These cells are comprised of 70% water with the remaining 30% containing varying proportions of structural and functional molecules such as proteins, DNA, and lipids.

Bone Hierarchical Organization

The intricate multiscale organization of the organic and mineral phases and the interaction between these phases, provides bone with impressive strength, stiffness and fracture toughness, while it is still a lightweight material. Bone has a complex hierarchical structure characterized by many functional units from the nanostructure to the macrostructure.

There are two types of bone tissue at the macrostructural level, cortical (or compact) bone and trabecular (or cancellous or spongy) bone, as shown in Fig. 4. Cortical bone is very dense as it has a low porosity of 5%–10%. It forms the thin protective shell surrounding the metaphysis and epiphysis of long bones, the outer shell of the vertebra, scapula and pelvis and the hollow cylindrical shaft for the diaphysis of long bone. At the micro-scale cortical bone is made up of functional units known as osteons. These are cylindrical structures that contain a central blood vessel in the Haversian canal, which is surrounded by concentric rings of osteocyte cells.

Trabecular bone, is mainly found within the metaphysis and epiphysis of long bones or within the central space of flat bones such as vertebrae, and is characterized by a high porosity (75%–95%) and a network of interconnected rods and plates called trabeculae. The majority of trabeculae are orientated along the same direction as the predominant mechanical stresses imparted on

Fig. 4 Hierarchical structural of bone. Reproduced from Vaughan, T.J., McCarthy, C.T., McNamara, L.M., 2012. A three-scale finite element investigation into the effects of tissue mineralisation and lamellar organisation in human cortical and trabecular bone. *The Journal of the Mechanical Behavior of Biomedical Materials* 12, 50–62.

bone (Frost, 1994; Wolff, 1986). On this basis, it has long been proposed that trabecular bone is organised so that internal stresses are distributed to the surrounding cortical bone (Rudman *et al.*, 2006), thereby enabling structural strength while minimizing bone mass (Wolff, 1986).

Mechanical Behavior of Bone

As a consequence of the complex hierarchical structure of bone, it is necessary to examine bone at various length scales to understand its mechanical behavior, specifically by conducting whole bone, structural-level and tissue-level characterization. Whole bone testing is conducted through traditional techniques, such as 3 or 4 -point bending (Akhter *et al.*, 2001) or compression testing (Akhter *et al.*, 2001; Lane *et al.*, 2006), to approximate the bones mechanical behavior at the organ level. However, mechanical properties at the organ level are influenced by the loading direction, bone geometry (which is unique at each anatomical region) and bone mass and therefore do not provide sufficient understanding of the bone as the material level. Furthermore, whole bone testing, describes mechanical behavior at the highest level of a complex hierarchical structural and therefore does not account for local material variation.

Structural Mechanical Behavior of Bone

The structural mechanical properties of cortical and trabecular bone are highly dependent on bone mass, 3D architecture and porosity, which vary considerably depending on the anatomical location and age of the tissue. Hence, the structural mechanical properties do not represent bone mechanical behavior at the material level and are often referred to as “apparent” mechanical properties. Engineering test methods such as uniaxial tension, uniaxial compression, torsion, tensile and compressive fatigue and 3 point bending have been conducted on millimeter-scale specimens of cortical and trabecular bone, to establish the influence of porosity, microarchitecture and bone mass on the structural mechanical behavior of bone (Carter *et al.*, 1981; Chang *et al.*, 1999; Ding *et al.*, 2002; Dong and Guo, 2004; Evans, 1976; Goldstein *et al.*, 1983; Hayes and Carter, 1976; Jepsen *et al.*, 1999; Keaveny *et al.*, 1993, 1997, 1994, 1999; Kopperdahl and Keaveny, 1998; Kopperdahl *et al.*, 2000; Kotha and Guzelsu, 2003; McCalden *et al.*, 1997; Mirzaali *et al.*, 2016; Morgan *et al.*, 2001; Nicholson *et al.*, 1997; Pattin *et al.*, 1996; Schaffler and Burr, 1988; Schwiedrzik *et al.*, 2017; Wachter *et al.*, 2001; Zioupos and Currey, 1998; Zioupos *et al.*, 2001).

As a result of the alignment of collagen and organization of bone tissue, the mechanical properties of cortical bone vary with the loading direction, whereby the cortical bone material is stiffer along the long axis of bone (14–22 GPa) (Carter *et al.*, 1981; Dong and Guo, 2004; Evans, 1976; Kotha and Guzelsu, 2003; Mirzaali *et al.*, 2016; Pattin *et al.*, 1996; Reilly and Burstein, 1975; Schaffler and Burr, 1988; Zioupos and Currey, 1998; Zioupos *et al.*, 2001) when compared to the reported mechanical properties (6–10 GPa) for samples tested in the transverse direction (Dong *et al.*, 2012; Dong and Guo, 2004; Reilly and Burstein, 1975). Apparent yield strength of cortical bone has been reported as 115 MPa in compression (Mirzaali *et al.*, 2016) and 72–129 MPa in tension (Carter *et al.*, 1981; Mirzaali *et al.*, 2016). The apparent ultimate strength values reported for cortical bone indicate that the

material is more resistant to fracture under compression (205 MPa) (Reilly and Burstein, 1975) and bending (158–191 MPa) (Zioupou and Currey, 1998; Zioupou *et al.*, 2001) and is weaker under tension (93–140 MPa) (Carter *et al.*, 1981; Evans, 1976; Kotha and Guzelsu, 2003; Mirzaali *et al.*, 2016; Reilly and Burstein, 1975).

Engineering approaches have demonstrated the variability in the structural mechanical behavior of trabecular bone across anatomical sites including vertebrae, humerus, distal and proximal femur and proximal tibia (Chang *et al.*, 1999; Goldstein *et al.*, 1983; Keaveny *et al.*, 1993, 1997, 1994, 1999; Kopperdahl and Keaveny, 1998; Morgan *et al.*, 2001; Nicholson *et al.*, 1997). These studies report range of values for the apparent elastic modulus of trabecular bone (30–2600 MPa), the apparent yield strength under compression (2–21 MPa) and tension (2–16 MPa), the apparent ultimate strength in compression (1–24 MPa) and tension (2–17 MPa). This variation in the apparent mechanical behavior of trabecular bone has been correlated to bone mass, 3D microarchitecture and tissue composition, which arise due to the variable loading demands between anatomical sites. Studies have demonstrated a variation in mechanical behavior depending on the direction a load is imparted on the trabecular structure, (Nicholson *et al.*, 1997). For example, the structural elastic modulus was found to vary significantly depending on the loading direction within a single vertebral bone, with highest modulus of 165 MPa in the supero-inferior direction and lowest modulus of 43 MPa in the lateral direction (Nicholson *et al.*, 1997). It has been reported that trabecular bone has 30% higher yield strength at 21.3 MPa in compression loading compared to 15.6 MPa in tension (Keaveny *et al.*, 1994). Trabecular bone has an apparent yield strain of 0.8% (Kopperdahl and Keaveny, 1998). Compressive loading beyond yield strain, followed by unloading and reloading, results in permanent residual strains and decreased stiffness and strength (Keaveny *et al.*, 1999). Hence, solitary incidents of overloading may not cause fracture on impact but can lead to accumulation of enough permanent damage to later cause clinical fracture.

The fatigue failure of trabecular bone has been found to vary within the typical range of physiological frequencies (0.5–3 Hz), with cycles to failure as low as 20 cycles at 2.1% strain and 400,000 cycles at 0.8% strain (Michel *et al.*, 1993). Since the structural mechanical properties of bone are highly dependent on the microarchitecture and bone mass (Ding *et al.*, 2002; Mosekilde *et al.*, 1987; Wachter *et al.*, 2001), they do not describe the mechanical behavior of the bone tissue as a material.

Mechanical Behavior at Tissue level in Bone

Tissue level studies are often carried out on individual trabeculae or microscopic sections of cortical bone tissue to characterise the mechanical behavior of the tissue, independent of bone mass or architecture. Such tests can capture the influence of the composite material comprised of organic proteins, hydroxyapatite crystals and other nanoscopic constituents of bone. In general, bone tissue can be described as an anisotropic, heterogeneous non-linear material and there are significant differences in mechanical behavior of bone tissue between unique anatomical sites as a result of the adaption at the tissue composition and microstructural organization at each region to the varied daily loads exerted on the body.

Many engineering test methods have been developed to characterise bone mechanical properties at the tissue level, such as 3 point bending, torsion, buckling, cantilever bending, micro-tensile testing, micro-pillar compression, ultrasonic measurement, acoustic measurement and nanoindentation have been applied to characterise the mechanical properties of bone at the tissue level, see Fig. 5 (Ascenzi *et al.*, 1994; Ashman and Rho, 1988; Bini *et al.*, 2002; Busse *et al.*, 2009; Carretta *et al.*, 2013; Chevalier *et al.*, 2007; Choi *et al.*, 1990; Franzoso and Zysset, 2009; Giambini *et al.*, 2013; Hengsberger *et al.*, 2002; Hoffler *et al.*, 2005, 2000;

Isaksson *et al.*, 2010; Jiroušek *et al.*, 2011; Kim *et al.*, 2014; Kuhn *et al.*, 1989; Lorenzetti *et al.*, 2011; McNamara *et al.*, 2006, 2005; Mente and Lewis, 1989; Mulder *et al.*, 2007; Nicholson *et al.*, 1997; Rho, 1996; Rho *et al.*, 1997, 1993; Ryan and Williams, 1989; Schwiedrzik *et al.*, 2014; Townsend *et al.*, 1975; Turner *et al.*, 1999; Wolfram *et al.*, 2010; Zysset *et al.*, 1999). These studies have reported a wide range of elastic modulus for trabecular tissue (0.75–25 GPa), though there is less variability in the elastic modulus reported for cortical tissue (14.5–27.5 GPa).

Finite element (FE) methods can be used to estimate bone tissue elastic modulus by combining 3D reconstructions of bone, derived from high resolution micro-CT scanning, with mathematical material models (often assumed to be linear elastic). An initial estimate of tissue elastic modulus is applied to the FE bone model and iterated until the stress-strain relationship output from the computationally simulated mechanical test corresponds to experimentally obtained stress-strain data. FE studies have estimated tissue modulus to be between 2.23 and 27 GPa for trabecular bone and between 17.1 and 21.7 GPa for cortical bone (Bayraktar *et al.*, 2004; Day *et al.*, 2001; Hou *et al.*, 1998; Ladd *et al.*, 1998; Morgan *et al.*, 2003; van Rietbergen *et al.*, 1995; van Ruijven *et al.*, 2003). However these FE methods predict the elastic modulus under the assumption that bone is an isotropic material and the resulting tissue modulus is often referred to as an “effective isotropic tissue modulus” which, does not capture the complexity of the heterogeneous material.

Bone mineral content is positively correlated with the material Young’s modulus (Bourne and van der Meulen, 2004; Currey, 1984, 1988, 2003; Rho *et al.*, 1995). The heterogeneity of bone mineral distribution has been investigated. Finite element models of trabecular bone cubes were applied to study the role of the in vivo heterogeneous mineral distribution by comparing it to a hypothetical uniform mineral distribution, whereby both models would produce an identical DXA areal BMD of 0.4 gHA/cm³. An exponential relation was assumed between local mineral content and tissue level stiffness and simulated axial compression of the trabecular cube model indicated that a heterogeneous mineral distribution increased apparent stiffness (average +15%) compared to a homogenous mineral distribution (van der Linden *et al.*, 2001). Other studies have assessed the impact of incorporating material heterogeneity in FE models of bone on the predicted apparent mechanical behavior, and reported that there was a decreased trabecular stiffness (–21%)(Renders *et al.*, 2008) or both decreased and increased stiffness, depending on the extent of the heterogeneity (Jaasma *et al.*, 2002), when compared to the assumption of a homogenous distribution of mineral.

It is possible that the natural heterogeneity in trabecular tissue mineral distribution can explain a certain degree of variability in the reported elastic moduli for trabecular tissue. Furthermore, a study combining bone mineral density distribution (BMDD) analysis of quantitative backscatter SEM images and three point bending of individual human trabeculae, found that increased mineral heterogeneity resulted in significantly decreased tissue elastic modulus, yield strength, ultimate strength and bending stiffness (Busse *et al.*, 2009). It should be noted that seemingly small spatial variations in bone composition, the presence of stress-concentrations such as osteocyte lacunae, and the “cement line” interface between adjacent bone lamellae, would have a large influence on the mechanical properties of the tissue at the microscale, due to the relatively low surface to volume ratio of a trabecular element compared to macroscale testing of a cylindrical volume of trabecular bone. Furthermore, nanoindentation of individual ovine trabeculae has demonstrated tissue elastic modulus and hardness increased with distance from the superficial layer towards the core of the trabecula, (elastic modulus: superficial 17.2 GPa, intermediate 21.7 GPa, core 23.4 GPa; hardness: superficial 0.29 GPa, intermediate 0.41 GPa and core 0.47 GPa) (Brennan *et al.*, 2009). Ultrasonic and micro-tensile testing of human trabecular and cortical samples have indicated that the elastic modulus of trabecular tissue (14.8 GPa $\pm$ 1.4 and 10.4 $\pm$ 3.5 GPa, respectively) was approximately 40% lower than that of cortical bone tissue (20.7 $\pm$ 1.9 and 18.6 $\pm$ 3.5 GPa, respectively) (Rho *et al.*, 1993). However, many studies have reported elastic moduli from nanoindentation of trabecular bone tissue ranging from 17.6 to 25 GPa (Chevalier *et al.*, 2007; Giambini *et al.*, 2013; Hengsberger *et al.*, 2002; Kim *et al.*, 2014), which are similar to elastic moduli found in cortical bone. In fact, a study using acoustic measurement and nanoindentation obtained moduli from human femoral trabecular tissue of 17.50 $\pm$ 1.12 GPa and 18.14 $\pm$ 1.7 GPa respectively, which was within the range of moduli obtained in the same study from cortical tissue in the transverse (14.91 $\pm$ 0.52 GPa and 16.58 $\pm$ 0.32 GPa) and longitudinal (20.55 $\pm$ 0.21 and 23.45 $\pm$ 0.21 GPa) directions (Turner *et al.*, 1999). These findings suggest that the distinctions in the microscale arrangement of trabecular and cortical bone tissue results in different mechanical behavior at the micro- and macro-scales.

Fracture Behavior

Bone has an innate ability to sustain microdamage without allowing failure to occur at the macro-level. Everyday activities such as walking and running incur large amounts of cyclic loading on our bones over many years, which result in accumulation of microcracks within the bone tissue (Norman and Wang, 1997; Schaffler *et al.*, 1995). Fracture behavior of bone is complex due to its organization as a composite material. Fractures appear in bone in the form of macro-level cracks or diffuse microcracks, which can emerge in both normal and extreme conditions, such as creep, fatigue or impact loads (Caler and Carter, 1989; Carter and Hayes, 1977; Schaffler *et al.*, 1995; Vashishth *et al.*, 2000). It has been shown that bone microdamage mainly occurs within interstitial bone tissue and grow towards the interfaces between adjacent lamellae, which serve as energy absorbers to resist growth of macro-level cracks (Boyce *et al.*, 1998). Large cracks, which are deflected along the lamellar interfaces, are observed alongside small microcracks which accumulate and spread to absorb energy from the largest crack, in order to slow down its propagation through the bone (O’Brien *et al.*, 2005). Fracture behavior in bone is anisotropic, with large crack growth occurring longitudinally, these cracks are deflected in the tangential direction, while microcracks in the radial direction increase toughness (Zimmermann *et al.*, 2009). This anisotropic fracture behavior is influenced by the

difference of fibre orientation in the collagen matrix of adjacent lamellae, which averts crack growth from continuing along a single fibre direction, i.e. the crack can only continue alongside the fibre direction within one lamella, as the adjacent lamellae will be oriented in a different direction and therefore deflect the crack propagation, see Fig. 5 (Schaffler *et al.*, 1994). The presence of accumulated micro-damage in bone tissue causes a reduction in elastic modulus and strength (Burr *et al.*, 1998; Carter and Hayes, 1977; Schaffler *et al.*, 1995). However, remodeling of bone is essential for preventing excessive build-up of natural microdamage, in order to preserve bone strength (Burr *et al.*, 1985; Lee *et al.*, 2000). It has been found that bone toughness, or resistance to crack growth, decreases with age as the tissue becomes more mineralized (Burstein *et al.*, 1976; Nalla *et al.*, 2004; Zimmermann *et al.*, 2011). High strain rates also reduce the fracture toughness of bone through reducing its capacity for energy absorption, as low strain rates are required for microcracks to form (Schaffler *et al.*, 1989).

Bone is a Remarkably Strong and Adaptive Material

The skeletal system is a remarkable material, whose composite hierarchical design serves to provide structure to the human body, protects the internal organs and transmits movement through its series of joints in collaboration with muscles, tendons and ligaments, and is lightweight yet remarkably strong. Unlike engineering composite materials, bone is a living and adaptive material, which has the ability to constantly renew itself to maintain its strength throughout life and can also redesign itself to optimize its function in response to the demands of external loads. This renewal and adaptive nature is facilitated by dynamic cell activity that can replace aged or damaged bone with healthy bone tissue.

Bone tissue is created and its strength is sustained by osteoprogenitor, osteoblast, osteocyte, osteoclast and bone-lining cells, each of which are vital in bone modeling, repair and remodeling. Osteoprogenitors are the precursor cells necessary to enable bone formation, because they can differentiate into osteoblasts when exposed to appropriate mechanical or biochemical cues (Okazaki *et al.*, 2002). These cells are active in the growing embryo, during childhood growth, but also reside in the bone marrow, periosteum and endosteum of adults throughout life so that they can be recruited to initiate repair processes to repair fractures when necessary. Osteoblasts make and secrete unmineralized bone matrix known as osteoid, specifically by synthesizing and assembling the tropocollagen molecule (see Section “Collagen” above), where it is packaged as a triple helix of three polypeptides and two short non-helical structures at each end called telopeptides. The packaged tropocollagen molecule is secreted from the osteoblast into the extracellular matrix (ECM). Meanwhile the non-helical telopeptide ends are removed by proteinases, which promotes aggregation of many tropocollagen molecules in the ECM. Bone lining cells are quiescent osteoblasts that line endosteal surfaces, which are known to be involved in bone remodeling by signaling to osteocytes and promoting osteoclast differentiation (Kollet *et al.*, 2006; Matsuo and Irie, 2008).

Osteocytes, which are the most abundant bone cell, are terminally differentiated. These cells play a role in remodeling, are mechanosensory and also can regulate calcium content in bone by remodeling their surrounding matrix (Bonewald, 2011). Osteoclasts are multinucleated, motile cells and are the only cells capable of resorping bone matrix when it is necessary to remove damaged or aged bone tissue during bone remodeling or repair.

Bone formation at any stage of life, occurs in one of two forms, intramembranous ossification or endochondral ossification. Endochondral ossification is carried out in embryonic long bones, the growth plate of immature bone and during fracture healing. Mesenchymal stem cells (MSCs) are differentiated into cartilage cells, called chondroblasts and create a cartilage matrix to serve as a template for bone development (Ortega *et al.*, 2004). The chondroblasts differentiate into chondrocytes, which promotes mineralization of the cartilage template, before they undergo programmed cell death, known as apoptosis. Empty cavities in the mineralized collagen template, previously occupied by chondrocytes, are infiltrated by blood vessels, which encourage the recruitment of osteoclasts and osteoblasts (Collin-Osdoby, 1994; Gerber and Ferrara, 2000; Sumpio *et al.*, 2002). The osteoclasts remove the underlying cartilage template and the osteoblasts replace it with new bone tissue. During early development, secondary ossification occurs at the end of long bones, which undergo vascularization and form a cartilage layer called the growth plate. Bone growth continues through childhood, by means of endochondral ossification at the growth plate, causing long bones to gradually increase in length. At a certain point in adulthood, this growth plate fuses and mineralizes into bone tissue, thus ending growth at the bone site.

During embryonic development, flat bones such as the clavicle and the skull are formed by intramembranous ossification. These bones do not require a cartilage template to initiate bone formation. Instead MSCs gather together to form an aggregate material which serves as a basic template for ossification. The MSCs differentiate into osteoblasts and deposit immature bone tissue, which is then calcified into woven bone and with continued remodeling cycles the tissue increases in strength and hardness (Chung *et al.*, 2004; Cowin, 2001; Kanczler and Oreffo, 2008).

Bone in Ageing and Disease: Osteoporosis

The mechanical integrity of bone becomes compromised during ageing or pathological diseases, such as osteoporosis. Increases in cortical porosity with aging has been found account for 76% of a reduction in the apparent material strength (McCalden *et al.*, 1993), while the apparent elastic modulus is reported to have a negative power relationship with porosity (Schaffler and Burr, 1988). The porosity predominantly affects the elastic modulus and shear modulus in the longitudinal direction, whereas it has

been found to be unrelated to the apparent behavior in the transverse direction (Dong and Guo, 2004). The apparent mechanical behavior of trabecular bone decreases during ageing, with almost 10% decrease in modulus and strength in the human femur and spine per annum (McCalden *et al.*, 1997). As people age there is a gradual loss of bone mass, but this process is more dramatic and accelerated during osteoporosis. This bone loss is a result of an imbalance in the bone remodeling process whereby excessive bone resorption occurs without satisfactory bone formation to replenish the lost tissue. As a consequence the bone structure is depleted, the mechanical integrity is reduced and susceptibility to fracture is increased. Severe fractures in advanced ageing result in immobility, pain, deformity and, potentially, a reduced quality of life.

Osteoporosis primarily occurs in postmenopausal women, with 40% of women over 50 at risk (Melton *et al.*, 2005) and produces the second most significant health threat in women after breast cancer, with an osteoporotic fracture increasing the risk of mortality by 10%–20% within a year of injury (Cummings and Melton, 2002; Melton *et al.*, 2005). Although, there is an link between decreased bone mass and reduction in mechanical strength of bone structures during osteoporosis, as demonstrated in testing of bone from animal models of the disease (Brennan *et al.*, 2012; Kennedy *et al.*, 2009), it is incorrect to assume the bone loss occurs systemically throughout the trabecular structure. In fact, a recent study has shown that while there is loss of trabecular struts in early stages in a rat model of osteoporosis, the struts that remain have increased thickness in the long term (Waarsing *et al.*, 2006).

Furthermore, loss of bone mass accounts for only 60% of the increase in bone fragility during osteoporosis (Ammann and Rizzoli, 2003). Thus, it has become increasingly clear that the heterogeneity of trabecular structure and bone tissue composition must also be a causative factor in the increased fracture risk. Studies have produced conflicting reports on the changes to bone tissue mineral content during osteoporosis, some observed unchanged or decreased mineral content in osteoporotic tissue (Guo and Goldstein, 2000; Li and Aspden, 1997), while others reveal and increase in tissue level mineral and increased heterogeneity of mineral distribution (Busse *et al.*, 2009). Osteoporosis has also been shown to affect the collagen content in bone tissue, with alterations occurring in the nature and quantity of collagen cross-links (Batge *et al.*, 1992; Mansell and Bailey, 2003). Increased heterogeneity of the mineralized collagen matrix, may potentially have a significant contribution to the risk of fracture in osteoporotic tissue by means of altered load distribution within the trabecular structure.

The impact of osteoporosis on tissue level mechanical properties has been investigated using bone tissue from osteoporotic humans and animal models, which simulates the conditions of postmenopausal osteoporosis. These studies have produced conflicting reports on the effect of osteoporosis on tissue elastic moduli, with nanoindentation studies indicating there is no change in stiffness of the lumbar vertebra (Guo and Goldstein, 2000) and proximal tibia of ovariectomised rats (Maimoun *et al.*, 2012) and the proximal femur of ovariectomised sheep in a model of long term osteoporosis (Brennan *et al.*, 2011b) compared to age-matched controls. Further nanoindentation studies and a three-point bending study reported decreased elastic modulus in osteoporotic tissue from the human iliac crest (Tjhia *et al.*, 2011) and vertebrae (Busse *et al.*, 2009; Kim *et al.*, 2014), lumbar vertebrae from ovariectomized rats (Maimoun *et al.*, 2012) and the proximal femur of ovariectomised sheep (Brennan *et al.*, 2009). However, another nanoindentation study and a micro-tensile study have reported increased stiffness in the human proximal humerus (Molino *et al.*, 2019) and the proximal tibia of ovariectomised rats (McNamara *et al.*, 2006). Aside from the possible contribution of differences between the experimental technique and anatomical site used in these studies, the variability of the reported effects of osteoporosis on tissue-level mechanical behavior may be a strong indication of the increased material heterogeneity in bone tissue due to osteoporosis.

Lessons From Nature: Natural and Synthetic Biomaterials That Mimic Bone

As described above, bone is a unique and complex material that exhibits exceptional biological and physical properties, but disease and ageing impair the tissue and so alternative materials have been explored for various applications including medical devices to replace degenerative bones or as materials that encourage bone repair within the body.

Metallic biomaterials were the first class of material considered to replace damaged bone, particularly in development of orthopedic implants to treat fractures and degenerative conditions such as osteoarthritis and osteoporosis. Stainless steel, cobalt chromium and titanium have been widely used in orthopedic implants (prosthetic hips, knees) because they provide high strength, fracture toughness, hardness, corrosion resistance and are biocompatible (Disegi and Eschbach, 2000; Ratner *et al.*, 2004). However, these materials exhibit substantially higher elastic moduli and so bear the load, and in doing so by-pass regions of bone in terms of force/stress transmission. Bone tissue is intricately linked to the mechanical demands, and bone cells activate a biological response known as “stress-shielding” to remove bone tissue in the absence of sufficient stress. Stress-shielding is a complication of orthopedic implants that can ultimately cause implant loosening and require revision surgery (Glassman *et al.*, 2006; Sumner, 2015; Uthoff and Finnegan, 1983). Moreover, metallic implants often need to be modified to prevent corrosion and wear, which can release toxic metallic ions that activate inflammation, and coated in proteins to encourage cell attachment for (osseo)integration of the implant (Bekmurzayeva *et al.*, 2018; Rony *et al.*, 2018). Porous metallic foams have thus been developed to enhance the match of the material properties to bone and prevent stress-shielding, and also to provide physical space for cell infiltration and osseointegration (Krishna *et al.*, 2007; Ryan *et al.*, 2006). These have been recently vastly improved by the accessibility of additive manufacturing techniques, such as rapid prototyping, selective laser sintering, selective laser melting, and electron beam melting, which facilitate production of complex porous structures (Lopez-Heredia *et al.*, 2008; Yuan *et al.*, 2019).

Bioactive ceramic materials, such as hydroxyapatite (HA) and tricalcium phosphate (β -TCP), exhibit certain mechanical properties and chemical composition that are similar bone (LeGeros, 2002, 2008), and for this reason they have been widely used

to replace bone tissue for orthopedic implants to overcome the issue of stress-shielding. These ceramics are biocompatible and bioactive, meaning that their composition enables degradation and release of calcium and phosphate ions that facilitate and induce bone formation by the host (osteoconduction, osteoinduction) (Barrere *et al.*, 2006; Rosa *et al.*, 2003). Hydroxyapatite can be processed to form porous structures that mimic bone microarchitecture using various approaches including ceramic foaming, polymeric sponges, gel casting, microwave processing and electrophoretic deposition (Li *et al.*, 2002; Sopyan *et al.*, 2007). However, ceramic materials are more brittle than bone and so are unsuited to skeletal locations where high impact loading is anticipated. Moreover, unfavorable cell behavior can arise, such as necrosis, if nutrients cannot reach the interior of ceramic materials. Calcium containing silica glasses also exhibit high strength, degradability and bioactivity (Jell and Stevens, 2006; Stevens, 2008), whereas marine species such as coral, sea urchins and sea sponges exhibit properties of bone because they produce calcium carbonate skeletons and these exhibit a natural porosity (Battistella *et al.*, 2012; Ivankovic *et al.*, 2010; Lekakou *et al.*, 2008; Mena *et al.*, 1979; Supronowicz *et al.*, 2011). Other ceramics like aluminum oxide, zirconium oxide or more recently silicon nitride or carbide are biologically inert and are used as permanent prosthesis material like hip or knee joints. Their main advantages compared to metallic or polymeric materials are their higher wear and corrosion resistance. More details are presented in other Encyclopedia chapters, these from Piconi and Tamperi on bioinert oxide ceramics and from Hampshire on non-oxide bioceramics.

Tissue engineering is a field that combines principles of biology and engineering to develop functional substitutes for damaged tissues (Langer and Vacanti, 1993). Naturally derived organic materials, such as collagen, glycosaminoglycans, gelatin, chitosan, silk fibrin, and elastin, have been widely used for bone tissue engineering (Dawson *et al.*, 2008; Harley and Gibson, 2008) because they mimic the organic components of the extracellular matrix and are biocompatible but also encourage cell attachment and matrix production (Harley and Gibson, 2008). Collagen-based scaffolds are widely used, due to the abundance and importance of the collagen protein in vivo for regulating bone cell growth and matrix production (Ben-David *et al.*, 2011; Chen *et al.*, 2007; Mullen *et al.*, 2013). Similarly, gelatin (denatured collagen) has been widely explored (Ben-David *et al.*, 2011; Jones and Cartmell, 2006). Glycosaminoglycans are proteins that exist in bone tissue and play a functional role in terms of providing attachment cues for bone cells, water retention and shock adsorption, and these have been added to collagen scaffolds at various concentrations to increase cell attachment and differentiation (Byrne *et al.*, 2008; Farrell *et al.*, 2007; Farrell *et al.*, 2006; Keogh *et al.*, 2010; Tierney *et al.*, 2009a,b). Elastin is also a naturally occurring organic protein that has been incorporated into collagen scaffolds to promote osteogenic differentiation and mineralization (Amruthwar and Janorkar, 2013; Çelebi *et al.*, 2012). However, natural polymers only serve to expedite or enhance the healing process by bone cells but they exhibit poor mechanical properties and so are not appropriate for applications where the load bearing function of bone requires immediate restoration. Chemical crosslinking of collagen/gelatin has been explored to address this limitation, but can only enhance the properties within the kPa range (Haugh *et al.*, 2011), and as such these materials remain deficient for implantation in load bearing locations.

Synthetic polymers (polylactic acid, polyglycolic acid) have been explored due to their availability, biocompatibility and the fact that their mechanical, physical and biological properties can be controlled to suit various applications (Gunatillake and Adhikari, 2003) (MacArthur and Oreffo, 2005; Yang *et al.*, 2004; Yang *et al.*, 2001), for example by altering the monomer ratios in copolymers (Murphy *et al.*, 2013). However, synthetic polymers also exhibit poor mechanical properties and can release acidic by-products and stimulate adverse tissue and inflammatory reactions (Murphy *et al.*, 2013).

Composite scaffolds have been explored to overcome the limitations of low mechanical stiffness of polymer based scaffolds and the brittle nature of ceramics/glasses. A variety of biologically enhanced ceramic and glass materials have been developed by combining them with bioactive materials such collagen, gelatin, RGD peptides, PCL, PLA, and these have been shown to simultaneously stimulate bone regeneration while having superior mechanical properties to polymers (Dawson *et al.*, 2008; Germanier *et al.*, 2006; Kanungo *et al.*, 2008; Lyons *et al.*, 2014; Tan *et al.*, 2014; Xu *et al.*, 2010; Yang *et al.*, 2004; Zhou *et al.*, 2007).
